Leg 3

27 September – 7 November 2007

edited and compiled by Jean-Éric Tremblay
(Chief Scientist)

1. General overview

1.1. Introduction

The participants of leg 3 express their gratitude to captain Lise Marchand and the officers and crew of the CCGS Amundsen for their unrelenting support and comprehension throughout the expedition. The present report covers both the ArcticNet (Leg 3A, 27 September – 18 October) and CFL (Leg 3B, 18 October – 7 November) portions of IPY leg 3 of the *CCGS Amundsen*. A SOLAS (Surface Ocean Lower Atmosphere Study) contingent was also present on board, bringing an additional atmospheric component to a predominantly ocean and ice-based science program. More than 20 distinct science operations were conducted on a daily basis and we successfully completed the inaugural dives of the ROV (remotely operated vehicle), which is now operational for scientific surveys (bottom and ice) and the recovery of moored instruments.

1.2. Science personnel

A total of 57 participants affiliated with at least one of the ArcticNet, CFL and SOLAS programs joined Leg 3 at one point. Most participants boarded in Resolute and stayed for the whole duration. The media crew from the Dan Rather Report (Dillon, Marx and Jones) disembarked in Nanisivik on 6 October. Three journalists from the BBC (Shukman, Georgiou and McGee) and a team from McGill (Lemieux and Tremblay B.) joined the ship in Resolute on 8 October. The BBC crew was flown to Kugluktuk on 13 October. Twelve scientists disembarked in Sachs Harbour at the end of Leg 3A on 18 October. At this time, 9 other scientists and the official CFL photographer (D. Barber) came on board for Leg 3B.

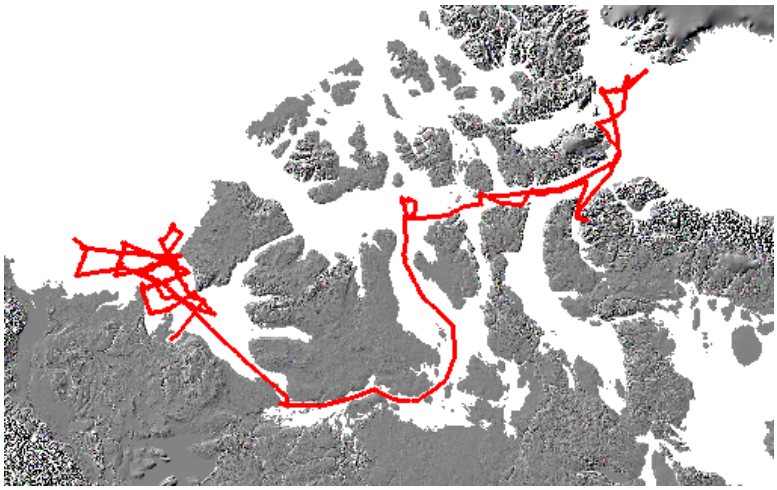
1.3. Cruise track

The map below was prepared by the Bottom Mapping Group and shows the ship's track from Resolute to Baffin Bay and from Baffin Bay to the Beaufort Sea. Sampling details (station coordinates, operations) and maps of the different regions are given in appendices. The break down of science operations in the different regions is given in the General Operation Log that follows.



1.4. General Operation Log

The charter flight left Quebec City on time at 06h00 on 27 September, despite some complications with the cargo. Contrary to the plan, supernumerary pallets of food had been loaded at the back of the cargo section early at night, which left little space for other scientific and Coast Guard cargo. Some of the supplies had to be left behind in Quebec City and plans were made to have a military Hercule plane deliver the supplies to resolute on 8 October. This plan never materialized and the initial loading incident had repercussions for the ship and the science program later during Leg 3. The exchange of personnel in Resolute went very smoothly, all the science and Coast Guard personnel was on board the ship for dinner time. The ship left Resolute on schedule at 18h00. A general meeting was held at 19h00 to introduce the captain, her senior officers and cruise participants to one another and discuss the chain of events for the leg and the next few days. A Power Point presentation detailing the various aspects of life, work and safety on board the *Amundsen* was also given.

The sea ice in the northeastern portion of Lancaster Sound and along Ellesmere Island considerably slowed our approach to station 101, which we reached 9 hours behind schedule. We did not have the option to start the North Water transect from the Greenland Side since the mooring instruments needed to be calibrated on Canadian land. The 40 hours of transit gave people the chance to prepare the laboratories, tune their instruments and get ready for sampling. A fire drill was also held. The liquid N_2 plant was switched on but was not operational before 30 September due to an electrical problem. We stopped only once to collect water for the drifting sediment traps and various teams that needed seawater for their initial preparations. After sunrise on the 29th the helicopter left early to bring Luc, Louis, Steve and Pascal on land for the calibration of compasses on the current meters (find position). They left early in the morning to make use of daylight while the ship was still miles away from station 101. Sampling operations began at 11h30 slightly off of station 101, where the ice conditions were impractical. Sampling activities were interrupted for mooring recovery attempt at 13:30. The ship slowly crawled to the mooring location, which was filled with aggregated flows of solid old ice (9+). Our assessment was that the ship would not be able to open and maintain a

sufficiently large hole to pop this long mooring safely. It was decided to postpone the operation for 5 days until the NOW transect had been completed (in case the wind turned and some of the ice cleared in the interval). We then crawled our way to Nutrient station 103 and Basic Station 105, which we completed successfully amidst the ice floes.

By then, we had realized that a freezer in which precious isotopes and chemicals had been stored frozen (microscopy room) in Quebec had been unplugged during the previous leg. The solutions were lost and the concerned people down south were informed of what had happened. Plans were made to bring new chemicals at the November 8 crew change. The SOLAS team lead by Ann-Lise Norman was not allowed to use the O_2 cylinder located next to the smoking area, which was considered a hazard by the captain. The cylinder had to be moved in the open space between the paleo lab and the benthos lab, which required soldering brackets on the bulkhead and drilling a hole through it. The whole adjustment took nearly two days to complete, delaying the start of Norman's gas chromatrograph.

On 30 September an examination of the moonpool in preparation for the ROV deployment at station 115 revealed the presence of a 2-feet thick slab of ice at the bottom. The ice was melted with hot water and salt water and the lower hatch was open to flush the ice residues once the ship got underway in ice-free waters. The MVP was deployed during the evening and we opted to tow it at 8 knots to keep on schedule (there was no requirements for this transect to be done at low speed and a high resolution). The deployment was plagued with many problems, the spots were out at the back and it took nearly 45 minutes to change the light bulbs. Then just after we put the fish in the water we lost one engine and it took another 30 minutes to get up to speed. The first half of the section went well, but then the system started to give a flurry of error messages. The system was re-initialized many times to no avail. The inital diagnostic was a sensor malfunction in the arm of the whinch.

Before arriving at mooring site BA-01 (sation 115), we held a meeting with Luc, Pascal, Vincent Auger, Michel (chief officer) captain Marchand and myself to discuss the ROV procedures and safety issues. Vincent had prepared a power point with the detail of the procedure. It was decided to operate with 2 deck hands (hold the cage and sub to stabilize), 1 winch operator, 1 crane operator and the Chief Officer or the Bosun (depending on the shift) to supervise from the moonpool and maintain a radio link with the Bridge. We deployed the floating sediment traps 2 miles west of station 115, which we reached early in the morning on October 1st. The location was surrounded by icebergs of various sizes, with several huge ones in relative proximity. The two acoustic releases on mooring BA-01-06 answered and were a few hundred feet away from the ship. We also got a response from BA-01-05. The exact location of BA-01-06 was determined over the next 45 minutes and the release command was finally issued. Both releases confirmed the command but nothing came up to the surface. The zodiac was deployed and we searched visually for the moorings during the next two hours, but saw nothing. Later the ship made a pass over the mooring coordinates (once in the morning and once just before we left station) and no line of instruments was visible on the EK60 echosounder. This is not a robust test, but given the presence of numerous huge icebergs it is plausible that the upper portion of the mooring was carried away.

We attempted the inaugural ROV deployment after lunch that day. Although a shallow dive of the cage and sortie of the sub was planned, glitches occurred during operations in the moonpool and it was decided to fix those before attempting a real dive. Specifically, the cage was not well balanced and tipped on its lateral vertical axis, which would have made it difficult for the sub to align the cage with the moonpool and could have made recovery extremely difficult or impossible. The time required to make the adjustments was estimated to one day, postponing the deployment until the next full station (108). Our tight sampling schedule did not make it possible to stay idle at station 115. The full suite of operations planned for that station was completed successfully and the ship sailed east.

After completing Nutrient station 113 and Basic station 111, we arrived at Full station 108 at 16h45 on 2 October. After discussing the mooring program with Louis Fortier and Yves Gratton it was decided to cancel the deployment of instruments initially planned for station BA02. This decision was

motivated by the modest success rate of recoveries in the North Water and the need to keep a margin of maneuver for the Beaufort Sea program. Because ice map showed that the Belcher Glacier and approaches were surrounded by ice, making bottom mapping impossible, 5 hours of mapping were inserted into the schedule of station 108 to make up for the lost opportunity and prepare for a future mooring recovery dive with the ROV. All the operations planned for this station were performed successfully, albeit for the failure of the 500 HP winch. By the time station 108 was done ice conditions at the site of the BA-03 mooring had not improved (9+ of old ice on October 3rd). These conditions and our tight schedule made a second journey and recovery attempt impractical. The ship headed for the Belcher Glacier while we performed MVP tests.

Waters close to the Belcher Glacier were ice-covered on 4 October, which made the bottom mapping attempt moot. We established the Basic station in Jones Sound to the southeast of the entrance to the Belcher Glacier. The visibility was poor and the ceiling was very low at sunrise. We waited another hour for more daylight and then launched the helicopter and the operations scheduled by Brad Danielson on the glacier were carried out successfully, but Brad experienced a problem with his met station and was unable to download data. Meanwhile we continued to perform typical operations for a basic station. A mishap then occurred with one of the Rosette cast. The captain and her third officer were on the bridge as the small hole the ship was in started closing in on the rosette - a large chunk of thick ice was coming directly at the cable while the rosette was near the surface. The chief officer on deck retracted the A-frame and the mutli-conductor cable leaned directly against the ship. No damage was done to the cable and the piece of ice was avoided.

During the evening of 4 October, the Rosette planned for station 300 was cancelled by the captain due to heavy wind, swell and currents, which made station keeping and a safe deployment very difficult. We then sailed for Nanisivik and docked on October 5 at lunch time. Dan Rather and his senior producer boarded the ship and performed two interviews and shots of the ship. In the afternoon several scientists and crew took a walk up the mountain in a large group. That night we organized a formal diner in the officers lounge. The tables were disposed in a u-shape fashion to allow people to interact. A balance was struck between senior scientists, officers, and students to make a representative cross-section of the participants. The diner was a success and Dan Rather and his producer left soon after to reach Arctic Bay before the snow storm got too thick to allow the truck's passage. The refueling *per se* was completed at 5 am on Saturday, but the seasonal draining of the tank and ferry of fuel to the ship by truck delayed our departure until 15h30. Nevertheless the operation was completed in 29 hours (30 were allotted). In the morning, a small bus came to the ship and picked up scientists and crew for a quick tour of Arctic Bay. A few Arctic foxes came close to the ship and seemed totally unafraid. In the afternoon a game was improvised with a homemade Frisbee. In the officers lounge we held a meeting with the captain, chief officer, Luc, Jacques Gagné and myself to discuss the upcoming deployment of the experimental mesopelagic trawl. Jacques presented a Power Point detailing the maneuvers. After some discussion concerning operations and safety we agreed to make the attempt. We left Nanisivik on October 6th, after 29 hours of refueling operations. We moved away from the dock and prepared to deploy the trawl. The deployment was slow and tedious, in part due to the nature of the operation and to the difficulties encountered to position the ship in the narrow passage. However, once the net was in the water the rest of the operation went smoothly and the retrieval was uneventful. Several hundred junevile Arctic cod were caught.

After the trawl we proceeded with the second deployment of the ROV in Admiralty Bay. The dive was very successful, the ship was able to maintain minimal drift, which allowed the pilots to dive on the bottom (see ROV section for detailed report). There they practiced observation and landing maneuvers over the sediment, which was thriving with epifauna. Near the end of the sortie it was Pascal's turn to dock the sub in its cage – he too passed with flying colors. The cage was brought back to the moonpool uneventfully. Congratulations were offered to the bridge for their navigation performance.

We performed additional MVP tests after the ship left Admiralty Bay. This time the problem was in the control box, where a connector was apparently not working. The ship then sailed toward Basic

station 301, which had been previously visited in 2006. We selected this station to make up for the lost opportunity at 300. We had planned a boxcore but it was cancelled due to an inadequate substrate. The team was allowed to look for an appropriate site and try again during the transit toward full station 302, but no adequate sediment was found. Full station 302 was completed successfully but some operations (VMP, RMT LAWAS, Phytoflash) were abandoned due to a mounting wind and snow storm. The substrate was also inappropriate for the boxcore, but the agassiz sled was highly successful, bringing on board a high biomass of diverse organisms. Soon after the ship started sailing toward Nutrient Station 304 the seas rose dramatically and the ship was rocked rudely. The bridge informed me they would make a turn and I awoke several scientists to make sure once more that all their equipment was well fastened. The ship then took a bend to the south and sailed under the relative protection of Prince Reagent Inlet until early morning, when a direct course was set for resolute. We lost roughly 6 hours because of the bad weather. Along the way, station 304 was cancelled and replaced by station 305 to make sure we would have enough time to ferry all the cargo and personnel from McGill and the BBC during daylight on 8 October.

The ship left Resolute for station 305 at 17h. A general meeting was held to introduce the new scientists and media crew, we discussed plans for the next few days and I gave the Life on Board power point to the new comers. During the discussions we considered the possibility of skipping station 312 and replace it by another west of Kugluktuk. Most people preferred to increase sampling resolution along the east-west gradient instead of getting a latitudinal section across McClintock Channel. Newcomers were taken on a familiarization tour of the ship the next morning (9 Oct) just before we began with the operations on Basic Station 308. The BBC crew then went into the zodiac to film Caroline's deployment of the SCAMP. Bruno's operation was not ready at that time and we were too far away from suitable ice flows. We decided to do it the next day and use the night to sail to the west in order to work in Viscount-Melville Sound. Later that evening the Radarsat image showed that the ice floes had compacted and we headed north and slightly west to avoid being trapped against the land south of Melville. We transited in a mixture of old heavy ice that needed to be rammed and thinner, soft ice. The ship halted at a safe distance from a large flow at around 3 am on 10 Oct and we started a basic station at this location. At daybreak the ship repositioned, we waited for the fog to lift and the helicopter left with Bruno, Jean-Francois and all their equipment for a nearby ice flow. They installed their first station and came back to the ship after lunch. The helicopter soon left again with Bruno, Jean-Francois, the BBC science correspondent (David Shuckman) and cameraman (Rob McGee). The operation was nearly 6 hours longer than anticipated (difficulty to locate an adequate site, drill problems) , but we compensated by sailing south much before the helicopter came back on board. Two polar bears were again sighted in front of the ship and people gathered on the foredeck to take pictures. The helicopter came back on board during diner and we held a steering committee meeting at 19h00. Bruno's operation was a success despite some technical problems. We decided to go to station 310 after a brief stop at an ad-hoc Box Core station (Boxcore A; 73 32.844; 103 17.934) to make up for the boxcore for the lost opportunity at station 309. Once station 310 was concluded we decided to cancel 312 (as expected) and sailed directly to station 314, where a short basic station was done. The shallow waters made it possible to satisfy the requirements of all teams with one rosette cast. We also deployed the Agassiz sled and the boxcore. The zooplankton team had no sampling interest there. That evening the scientists and crew gathered in the officer's lounge at 19h00 and said farewell to the BBC team. Gifts were exchanged and then a short video prepared by Rob was shown for the benefit of everyone. We were all very pleased with the humor and quality of that short piece of art. I then gave a talk on the general objectives of ArcticNet and the work done by the marine productivity team on board.

We then transited straight to a sheltered position to the northwest of Kugluktuk in order to tie up with the Louis Saint-Laurent. We were supposed to arrive on 13 October in early morning but the very high seas again delayed us by 5 hours. We tied up to the Saint-Laurent at noon and spent the next six hours bringing cargo and pumping our oily waters on the Saint-Laurent. Meanwhile, David, Rob and Mark from the BBC were flown to Kugluktuk. I held a short meeting to discuss plans for the next few days. Because the high seas, Bruno's operation and meeting with the St-Laurent had already used up our contingency time after departing Nanisivik and it was decided to sail directly for the westernmost

line (400) in the Beaufort Sea. On the morning of the 14th Jacques was standing by to deploy the trawl if significant fish biomass appeared on the echosounder, which unfortunately did not happen. The ship slowed down at ca. 11h00 to allow the DMS team (121 13) to take a bucket of water for their experiments.

The weather forecast was once again not very good with winds from the north east turning to the north east with gusts in excess of 35 knots. We made use of the transit time to fix the 500 HP winch and test the MVP again. This time there were problems with the main terminal connections in the box. We arrived at Basic station 434 at 9 am on 15 October and launched the helicopter with the 3 mooring technicians for calibrations on land. In the mean time we finished operations at station 434 at 15h00 and waited a little to hear back from the helicopter which had a minor mechanical problem on its way back from Inuvik (where our logistics officer, Lyne, left the ship for family reasons) to pick up the mooring technicians. We started sailing to station 433 as soon as 434 was done and the helicopter met us along the way. The line of CTD stations went well and we did a boxcore at station 428. Then we started operations at mooring station 435. The winds were picking up but things were still manageable until a rogue wave drenched the aft deck at around 07h00. It totally submerged the MVP control unit and flooded the aft labs via the ventilation system. Fortunately, no electrical problems were detected then. A deck hand was hurt in the process as he was swept by the wave and knocked his calf. He fully recovered. The Hydrobios cable was strained when the instrument slammed against the wave. Science operations were immediately put on hold and the CO_2 flux tower was brought done as we turned west and drifted for a few hours while tending to the ship. During the wind event a door slammed into the oxygen regulator (new installation, see above) and smashed it. There were no replacements on board but the SOLAS teams was able to use compressed air instead. Meanwhile we tried to communicate with the Tug in charge of the barges, but to no avail. We heard from the Coast Guard radio in Inuvik that the tug was southwest of Sachs Harbour but his could not be confirmed. Meanwhile we recovered parts of Geneviève's traps (the reflector, beacon and Argo float). These instruments were drifting seperately and no longer joined by a rope, which was presumably cut by a piece of drifting ice. Since we could not ascertain the position and status of the barge we waited for the winds to abate and the weather to improve sufficiently to attempt the mooring recovery. During the evening we sailed to mooring CA-04 and interrogated the releases. We had an erratic answer that suggested the mooring was nearly 2 kilometers off the mark. The weather was still too bad to attempt a recovery so we waited until the morning to try to get a more accurate location. In the morning one of the release answered only once with a signal that did not make much sense. We spent the next 2 hours searching for it with the ship and the zodiac which had the second deck unit. A salvage operation with the ROV was not feasible given the persisting wind and swell. We then prepared the new mooring while finishing the other operations planned for that station. The zodiac had problems with the cold and we could not do the SCAMP – it was fixed later during the day and was ready on time for the mooring deployment, which went very well. As soon as we finished triangulating the mooring we interrupted the rest of line 400 and sailed directly for Sachs harbour. Due to the time lost to bad weather and in the off chance that we would find the tug in Sachs Harbour, the community visit was postponed.

Once in Sachs we sent the mooring technicians on land to calibrate their instrument and started helicopter flights to exchange the people that left and came to the ship. Six of the newcomers did not have their scientific equipment and personal luggage when they came on board. These items were lost by First Air on the way in. All attempts at communicating with the airline on that day and later during the weekend were vain. In the mean time we located the barges, which were anchored in Summer Harbour. There was a Gale Warning and freezing spray warning in effect for this region and we were told that the tug would wait until conditions improved to cross the Gulf. We raised the anchor at 22h30 and proceeded to mooring station 437. We started with a series of nets but the sea state degenerated rapidly under the influence of easterly winds and we had to stop operations at around 3 am.

Given the equally bad weather forecast for the next day we headed north to do the line from station 1806 to 1800 under the protection of Banks Island. According to the coordinates given in the cruise

plan, these stations were much too shallow (less than 20 m of water under the keel) to conduct most science operations. The line was moved 18 miles to the west in order to have enough water to work. The first officer decided not to put the Zodiac in the water (SCAMP) due to cold weather and the rapid formation of new ice (a hazard when the zodiac is idle). We completed full station 1806 and proceeded to the south until we reached station 1800, which was done as a basic. In the morning we headed to station 437 (CA-16) to assess conditions. Things were still rocky but the mooring deployment was feasible. We resumed the sampling ops that had been cancelled the night before (rosettes) while the technicians prepared the mooring. CA-16-2007 was deployed successfully. The weather was still too rough to deploy the adjacent MMP in darkness and in order to save time we proceeded to the south and sampled a few CTD stations until daylight. We returned on site MW-2 to deploy the MMP. The deployment went smoothly except near the end when the ship was drifting over deeper waters. Luc expressed the will to release the weights in shallower waters, but this seemed to be problematic for the bridge so we dropped the wheels in 303 m before drifting over deeper waters. We then resumed sampling along line 400 until we reached mooring station 437 (CA-05). All the operations typically done at full stations were performed and the new mooring was deployed and triangulated. A CTD cast was done soon after the deployment. We then moved to site MW-1 for the MMP deployment, wich was done in darkness in 304 meters of water (target = 305 m). As several CTD cast had been done in the past 24 hr around the position we did not have time for another one.

We then proceeded east along the central line and reached mooring station 407 (CA-08) in the morning. The mooring did not answer and we started planning a ROV dive for the next day, while performing all the other operations on site. A survey of the bottom was done during the night, both for mapping purposes and to identify potential pitfalls for the ROV dive. After recovering the traps and performing a last rosette cast for the DMS people we proceeded with the maneuvering tests and ROV deployment. The dive went very well, all the bottom area around the assumed position of the mooring was surveyed visually and with the sonar, but the train wheels were not found (see separate dive report). Some traces that could have been produced by a dragged mooring were seen, but the evidence is inconclusive. All we could determine was that the mooring no longer resided within a 100-m radius of its triangulated position (which has a precision of 10 meters). A RCM-11 current meter initially positioned higher up on the line showed an abrupt descent from 120 to 340 meters on 16 May 2007. Since we were getting short on instruments, we did not deploy a new mooring at CA-08 right away, waiting to see what would be recovered on CA-18.

We proceeded along a series of CTD and nutrient station toward the next mooring site, 405 (CA-18). Sampling operations began during the night and paused in the morning for mooring recovery. The releases answered and the mooring was triggered. It took a long time to come up and, unfortunately, the white mid-water buoy came up first. It turned out that the upper section of the mooring were no longer present. The Kevlar rope was damaged and the rings on the buoys were deformed by strain – a possible sign that the ice ablated the top portion of the mooring. So far, the evidence gathered at CA08 and CA18 points toward an unusual year when rafting may have been more intense than usual. The decision was taken to lower the top instruments by 10 meters on the new CA-18-2007 in order to increase our safety margin. The new mooring was deployed smoothly in the evening of 25 October and we proceeded east with CTD stations and Basic station 1000.

Then we moved close to Banks Island to do Basic station 1100 and proceeded south with a series of CTD and Nutrient stations. We then completed Basic station 1110, a CTD and a Nutrient station and arrived at Full station 1116 in the middle of the night on 28 October. There was a fair amount of new ice at this station and some operations were canceled (Tucker, RMT). As it was impractical to use the zodiac, the SCAMP was deployed from the moonpool. Once the station was completed it was not possible to deploy the MVP in ice, and so we added three new CTD stations (1118, 1120, 1122) on the way to full station 1216. Boxcores were done at stations 1120 and 1122 to see if a spatial gradient in benthos community richness existed toward the hotspot. On arrival we spent 8 hours mapping the target ROV deployment site, which was slow and tedious with the ice and strong currents. These strong currents were oriented to the northwest and, along with winds of 25-30 knots and drifting ice floes, made it impossible to hold the ship in position for the ROV deployment. This activity was

canceled and other operations planned for that station were moved forward. We then started line 1200 towards Bank Island (series of CTD and Nut stations). While doing so we heard from the tug captain that he would leave Holeman in the late evening and possibly be in Summer's harbour in the evening of Oct 31, so we made plans to go meet them once station 1200 was completed. Mooring CA08-06 was interrogated from stations 1210 and 1208 and 1206 in case it had drifted south or north from its triangulated position. The mooring answered at station 1208 and we spent the next 2 hours triangulating it. The operation was difficult amidst winds of 40 knots and drifting ice and it look a long time to obtain a valid set of coordinates. The new ice and strong winds made any recovery attempt unthinkable at the time, but the coordinates can be used next year as a starting point for the search. Based on the new triangulated position the mooring has been dragged north by x miles. From there we proceeded north along the line of CTD and nutrient stations and completed station 1200. We experienced problems with the valve of the 500 HP, which had frozen again. Plans were also discussed during the day to improve the system used to thaw ice in the moonpool.

Upon completing station 1200 we learned that NTCL had not instructed the tug to meet with us in Summer's Harbour and a series of actions were taken to make sure that the proper authorities push the file. It appears the NTCL had decided to leave the barges in Summer's harbour weeks ago and did not inform anyone at Coast Guard, ArcticNet or CFL. Since we did not hear anything more for NTCL we decided once again to carry out the science program and move west to complete lines 1500 and 1600.

On November 1st we contacted Paulatuk to see if there was an interest for a community visit and the response was very enthusiastic. We also completed line 1500, but were slowed down by a rosette malfunction (the carousel skipped several position) and then twice by engine problems (a total of about 1 hour altogether). With the high winds and cold temperatures we had been experiencing several glitches with the Rosette. We looked into solutions that had been used during leg 8 of CASES – but the heater in the Rosette shack did not seem to be able to maintain proper temperatures. Since the complete grid of stations planned for the open water leg has been completed anyway we decided to migrate rosette ops to the moonpool after the completion of line 1600. The migration was performed during a period of 24 hr (November 2, 3). This time was also used to build a new shed for the Dave's instrument – the original shed was taken apart during the health survey, presumably to provide the bridge with a better visibility for barge operations. We used this welcome break in sampling activities to hold a Halloween party on Saturday night. The splicing, installation and testing of probes took most of Sunday and activities on line 1900 resumed during the evening of the 3rd. Operations were interrupted at around 2h30 am due to engine problems. A low water level in the sea bay caused one engine to overheat. It took almost 3 hours to fix the problem, run tests and sail back to Basic Station 1908 (the ship had drifted during the interruption). This station was completed in the morning of 5 November and we performed two CTD stations on the way to our last Basic station, 1916. We were supposed to receive the new 212 helicopter that day, but the bad weather in Inuvik delayed its flight to Paulatuk. Early in the evening the multi-conductor cable of the rosette got stuck in the cable guide and was kinked in a few places. The cable also made a dent on the side of the guide. As the necessary repairs (re-splicing, machining of a new part of the guide etc…) could not be completed until the next day we canceled rosette operations for Basic Station 1916 and the last two CTD stations of line 1900. Once other operations were completed at 3 am on 6 Novemberr, the ship sailed for Paulatuk.

Preparations were made for the community visit and the new 212 helicopter arrived on board just after lunch. In the evening we hosted 14 elders. Activities included a tour of the ship, shopping at the canteen, a formal diner (mix of community members, HTC, coast guard and scientists) and a presentation of the CFL project and the Amundsen. The event was very pleasant and the interactions were rich and positive. Teenagers from the local school came on board in the morning of 7 November and were taken on a tour of science and navigation stations around the ship. In the afternoon we started moving cargo to Paulatuk in order to fill the twin otter that returned to Inuvik later during the night. Videos and a slide show were presented in the evening and everyone resumed their packing for the crew change wich started early in the morning of 8 November.

2. Team reports

2.1. Seabed Mapping (ArcticNet 1.6)

PI: John Hughes Clark (University of New Brunswick)
Participants: Steve Brucker & Doug Cartwright (University of New Brunswick)

Introduction
The Ocean Mapping Group (OMG) was on board Leg 3 to perform seabed mapping as part of its role in the ArcticNet project. The primary purpose of the mapping on this leg was to collect as much bathymetry and sub-bottom information as possible while transiting between science stations throughout northern Baffin Bay, the Northwest Passage, and Amundsen Gulf / Beaufort Sea. Inclement weather was fairly common, as was the presence of both multi-year and newly formed ice. These attributed to the loss and/or degradation of data.

Equipment
CCGS Amundsen
Kongsberg-Simrad EM300 30 kHz multibeam echosounder
Knudsen K320R 3.5 kHz sub-bottom profiler
Applanix POS/MV 320 motion and orientation sensor
C&C Technologies CNAV GPS
Surface sound speed probe (temporary replacement)
Seabird SBE911 CTD, deployed from rosette

Onboard Logging and Processing Procedures
Multibeam and sub-bottom profiler collection began upon boarding the Amundsen near Resolute. CNAV GPS was logged separately, first on the SIS PC, then on the Knudsen PC. Both the multibeam and sub-bottom systems were logged continuously throughout the entire leg save for two days (Nov. 1 & 2) when the sub-bottom transducers were being acoustically isolated.

The EM300 data were logged in the Kongsberg-Simrad raw format and converted to the OMG format after line completion (new survey lines were automatically generated every half hour). The soundings were cleaned and inspected in near real-time with the two crew members maintaining a 24-hour watch throughout the cruise. Backups of the raw and processed data were made every few days onto DVDs (though they were copied to the processing computer in near real-time and mirrored to a second internal hard drive on a nightly basis).

The K320R data were logged in the Knudsen binary format (.keb). Data were converted to OMG format and then backed up in the manner mentioned earlier.

The CNAV data consisted of NMEA strings and was captured to a text file using HyperTerminal, with a new files being created at approximately midnight (GMT) every day. At the end of each day (GMT), this data was backed up to the processing computer and converted to OMG format. The data were then plotted geographically for visual inspection.

For surface sound speed, the probe data was logged and utilized real time by SIS at the beginning of the trip, with the probe malfunctioning about a week in. Sound speed profiles (Rosette CTD) were collected at each station. Raw files (collected in binary format) were converted to text files, copied to the processing PC and finally converted to OMG format, at which time the profiles were visually inspected for spurious data points. High resolution CTD casts were decimated to 1-metre bins using a median filter. Profiles were tagged with time and ship's position in real-time. If CTD profiles did not extend to full ocean depth, they were extended using the SVP editor in the SIS software package before being input to the EM300 logging software. Post-processing of the multibeam soundings with respect to sound speed profiles will be done upon return to UNB.

Mapping Procedures & System Performance
During transit between stations, coverage from previous transits was loaded into Aldebaran. This allowed the helmsman to steer coverage and build upon the previously collected data.

Several surveys were accomplished at the following locations:

- Northern Baffin Bay, NE of Stn. 108.
- Stn. 1216, Franklin Bay

Multibeam data quality was good in most cases, but severely degraded or even non existent during heavy swell and sea ice. Sub bottom data was generally good under most circumstances including ice breaking and heavy seas. Survey line running was at times freehand, with the helmsman steering coverage to maintain overlap between adjacent lines, but mostly performed with the use of survey lines plotted on either Aldebaran or SIS.

The SIS (EM 300) PC crashed on Thursday, October 4 at approximately 0900 utc. We were not able to power up the PC and after several hours of debugging by OMG and Laval staff, the PC was declared dead. We installed SIS on a spare laptop, entered the necessary offsets and successfully logged data. The laptop was used until 0200 utc on October 24th when a spare Kongsberg PC (HWS-11) was found aboard. This was an upgrade to the previous PC (HWS-10).

2.2. Team 1

2.2.1. Physical Oceanography

PIs: Yves Gratton[1], Peter Galbraith[2], Daniel Bourgault[3] & Rick Marsden[4]
Participants: Caroline Sévigny, Véronique Lago & Amélie Janin[1]

1. Centre Eau, Terre et Environnement Institut national de la recherche scientifique Université du Québec 490 de la Couronne, Québec (Qc) G1K 9A9 CANADA
2. Institut Maurice-Lamontagne Pêches et Océans Canada, 850, route de la Mer Mont-Joli (Québec) CANADA G5H 3Z4
3. Memorial University of Newfoundland, St-John's, CANADA NLA1B 3X7
4. Royal Military College of Canada, Kingston (Ontario) CANADA K7K 7B4

Water structure and ocean circulation

Véronique Lago & Amélie Janin

Objective

To describe water masses and the general oceanic circulation in the North Water Polynya, the Northwest Passage and the Beaufort Sea.

Methods

Water from the rosette was collected by different teams. Here are examples of usual depths of bottle closure.

- *Nutrients* (Jean-Éric Tremblay team): chlorophyll maximum, 10m above and 10m under chlorophyll maximum, salinity of 33.1, 5, 10, 20, 30, 40, 50, 60, 70, 80, 100, 120, 140, 160, 180, 200, 250, 300 and every 100 m up to the bottom.
- *Primary Production* (Michel Poulin, Gosselin and Christine Michel team): chlorophyll maximum, 100m, 75m, 100%, 50%, 30%, 15%, 5%, 1% and 0.2% of light mesured with a secchi disk before the cast.
- *Contaminants* (Gary Stern team): 4, 5, 7.5, 10, 25, 50, 100 and 200 m
- *Mercury* (Gary Stern team): three water masses, one at the top, one at the middle and the last one at bottom.
- *DMS* (Maurice Levasseur team): chlorophyll maximum, 50%, 15%, 5% and 0.2% of light measured with a secchi disk before the cast.
- *DIC* (Helmut Thomas team): 0, 5, 10, 20, 30, 40, 50, 60, 80, 100, 120, 140, 160, 180, 200, 250, 300 and every 100m up to the bottom.
- *CDOM* (Pierre Larouche team): 60m, 50%, 30%, 10% and 1% of light measured with a secchi disk before the cast.

Physical parameters were recorded using a ship mounted RD Instruments Ocean Surveyor ADCP, a Brooke MVP 300 and a rosette frame equipped with 24 bottles of 12 L and the following sensors:

Table 1 : Sensors used on the Rosette

Item	Manufacturer	Type	Serial Number	Max. depth [m]
CTD	SeaBird	SBE-911		6800
Temperature			4204	
Conductivity			2696	
Pressure			90584	

Oxygen	SeaBird	SBE-43	0427	7000
pH	SeaBird	SBE-18	0452 switched to 0444 on cast 024	1200
Nitrates	Satlantic	MBARI ISUS	132 switched to 134 on cast 143	1000
PAR	Biospherical		4664	
SPAR	Biospherical		20147	
Fluorometer	Sea Point		2465	
Transmisometer	WetLab		CST-558DR	
Altimeter	Benthos		1044 switched to 1061 on cast 028	

Sampling regions

CTD cast were done in Baffin Bay in NOW study area, outside Belcher glacier, along Northwest Passage and in Beaufort Sea, in the CFL study area. MVP was used once in Baffin Bay, but the transect have not been completed because of problems with the MVP. The hull ADCP recorded all the time from Resolute Bay to Paulatuk.

Figures 1, 2 and 3 show CTD cast positions in Baffin Bay, Northwest Passage and in Beaufort Sea. Figure 4 show positions of every CTD cast that have been done during cruise.

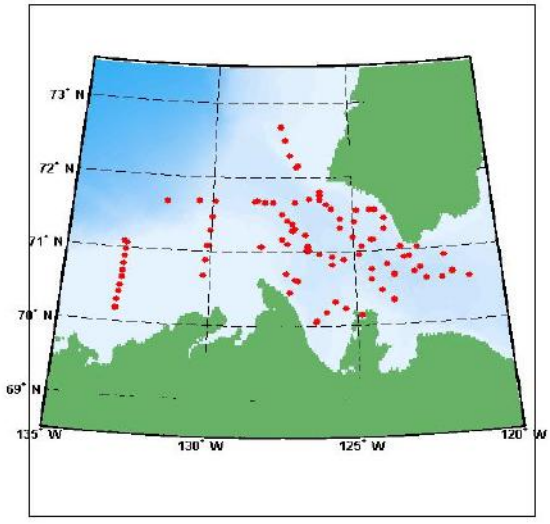

Figure 3: CTD casts in Beaufort Sea

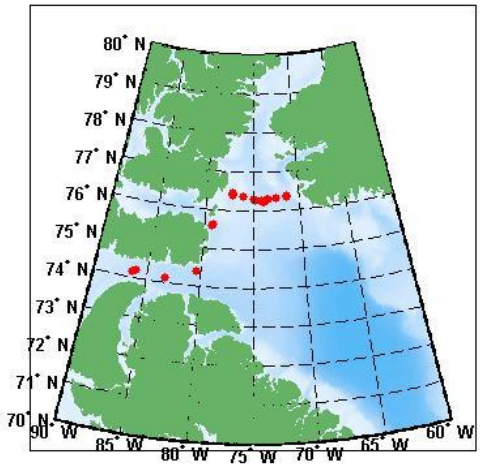

Figure 1: CTD casts in Baffin Bay

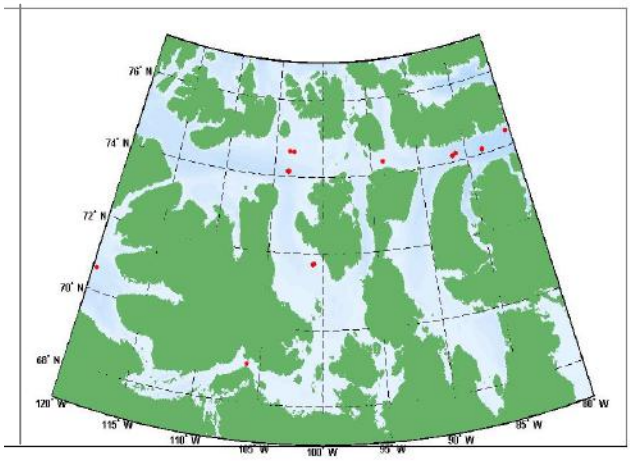

Figure 2: CTD casts along Northwest Passage

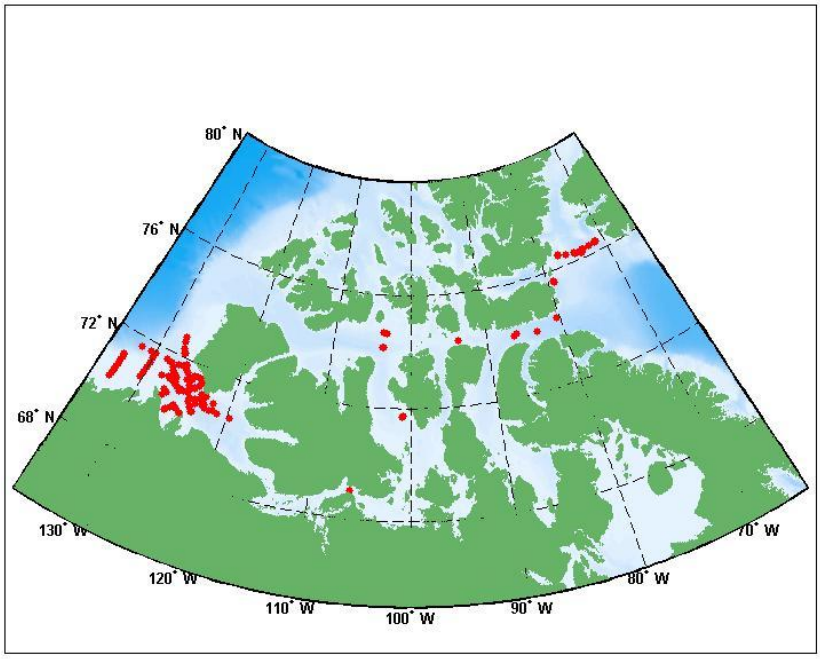

Figure 4: CTD cast done on leg3, cruise 0706

Available data
All information concerning the Rosette casts are summarized in the CTD Logbook. It includes cast and station numbers, date and time of sampling in UTC, latitude and longitude, bottom and cast depth, comments concerning the cast and its name. A Rosette sheet was also created for every single cast. It includes the same information than the CTD Logbook plus the bottle distribution among every sampling team. The weather information is written in every Rosette Log as well as in a meteorological logbook. For every cast, data recorded at the moment of bottle closure were averaged and recorded in the so-called 'bottle files'. Averaged data are those recorded between 3 seconds before bottle closure and 7 seconds after it. It includes the bottle position, time and date, pressure, temperature, salinity, transmissivity, chlorophyll, oxygen, irradiance and pH measurements. All those files are available on the 'Shares'.

- Rosette sheets and the CTD logbook : Shares\leg3\Rosette\logs
- Bottles files : Shares\Leg 3\CTD_Cast \BtlFiles
- Plots of every cast including salinity, temperature, oxygen, transmissometer, nutrients, fluorometer and irradiance : Shares\Leg3 \CTD_Cast\plots

Between September 28th and November 8th, 2007:
- 143 CTD casts were performed with the rosette
- ADCP data have been taken all along North Water Polynya, Lancaster Sound, McClintock Channel and Beaufort Sea
- A portion of the transect crossing North Water Polynya from Ellesmere Island and Greenland have been done by the MVP

Probes calibration
pH: Tests were done twice using two buffers. One is pH 4 and the other is pH 7. Results were quite good and consistent.
Salinity: Samples were taken on many contaminant's sampling casts as well as mooring stations nutrients casts. They have been analysed with a GuildLine autosal in October. Results were not very much satisfying. A rosette cast (cast 139) have been compared with a SCAMP cast and conclusions are that there is probably an offset on salinity data from the rosette. The data would probably need to be corrected.

Oxygen: Oxygen calibration was perform using Winkler's method and a Mettler Toledo titration machine. Reagent Blanks were performed twice, results show that chemicals are good (m<4). Oxygen samples were taken seven times, results are quite good.

Problems
- Sensors

Most of the sensors worked well for the whole cruise. The pH got some problems because of water intrusion in cables, the altimeter got some problems for a still unknown reason and the nitrate sensor stopped working properly by the end of the leg.

- Bottles

Two bottles have not closed a few times on the beginning of the leg, bottles 13 and 23.

- Deck material (winch, A-frame, etc.)

The winch overheated once. We already had the same problem on previous legs.

Turbulence

Caroline Sévigny

Introduction and General Objectives

The turbulence is usually defined as the irregular, random component of the fluid motion. In the seas and the oceans, this phenomenon is mainly associated with sheared flow induced by breaking internal waves. The resulting ”eddies” generated by this flow them-shelf induced strain that enhanced the production of overturns at smaller scales and so on to viscosity. This energy cascade (primarily directed toward smaller scales) promote scalar mixing, the ending of turbulence. While this process occurs in the upper ocean layer (< 100 – 150 m), it promotes pollutants dispersion, growth and vitality of marine organisms (especially plankton) and transfer of momentum, heat and gases across the surface.

To date, only few studies have tried to understand and to quantify the turbulent processes in the Arctic Ocean. Most of them deal with the special case of Barrow Strait [Melling *et al.*, 1984, Crawford *et al.*, 1999,Marsden *et al.*, 1994], a strait knew as highly active in term of vertical transport and mixing. Some other projects as the *Coordinated Eastern Arctic Experiment* (CEAREX, conducted east of Greenland; [Padman & Dillon, 1991]) and the *Lead Experiment* (LAEDEX, conducted north of Alaska; [McPhee & Stanton, 1996]) had also focus on the physical characteristics of turbulence in other arctic regions. Those works had brought some answers (i.e. the role of diurnal tides and high frequency internal waves), but did not clarify the problem for the whole Arctic. The general objectives of this study is then (i) to sketch a general pattern of active turbulence in the High Arctic and the Baffin Bay, (ii) to identified the main physical processes responsible of the observed mixing and (iii) to specified the role of turbulence in term of biological production.

Methods

The turbulence act first on the velocity field: the propagating waves create line vortices which continuously advect each other in complex ways. As those complexes structures are relatively stable, the mixing meanly occurs in region of intense strain created between any nearby vortices. The large resulting velocity gradients at small scales (1 mm to 1 cm) can be detected by air-foil shear probe, a piezo-ceramic bender that generates an electrical charge in response to cross-axial forces. The signal collected by this probe (u') and then, the deducted shear (du'/dz) can be used to estimated the rate of loss of kinetic energy under turbulent event ($\varepsilon \propto (\partial u'/\partial z)^2$, Wkg^{-1} or m^2s^{-3}), a parameter ranging from 10^{-10} Wkg^{-1} in the deeper part of the oceans to 10^{-1} Wkg^{-1} in the more active regions. A *Vertical Microstructure Profiler* (VMP) equipped with two similar probes have been used in this ArcticNet/CFL cruise to sample the turbulent vector field in open water. This profiler was deploying at each basic (30 min) and full stations (60 min) for a sequence of profiling. As the turbulence is most understood by statistical analysis, the profiling sequence is essential to predict the intensity and the characteristics of the turbulent flows. The VMP falls at a rate of $0.6ms^{-1}$ and has a sampling rate of 512Hz, which allows a measure at each millimetre. It is also equipped with a conventional Sea-Bird CTD (*Conductivity, Temperature and Depth* sensor, sampling rate: 64 Hz) and two fast response thermistors (sampling rate: 512 Hz).

As the vortices are created, the scalars fields (i.e. temperature) are compressed by the strain create between the turbulent structures of the flow. The scalar variance is then driven to smaller scales via eddies as the energy cascade goes on. As soon as they are formed, those thermal anomalies are blend into the background by molecular diffusivity at a rate χ, the rate of loss of thermal variance ($°C^{-2}s^{-1}$). It is the far end of turbulence, the smaller possible tracks of overturns. This turbulent mark can be detected by the *Self-Contained Autonomous Profiler* (SCAMP), a profiler designed to directly estimate the thermal variance produced by diapycnal mixing. This instrument has two fast response thermistors to measure the temperature gradient at every 0.01 s. As it falls at a rate of 0.1ms−1, the resulting precision is of 1mm, which is sufficient to resolve the complete scalar spectrum and to estimate $\chi \propto (\partial T'/\partial z)^2$. The SCAMP is also fitted with PAR, accurate T, accurate C, pressure and fluorometer sensors. This complementary instrument has been used in profiling sequence mode at some basic (deployed from the moon pool, 90 min) and full stations (deployed from the zodiac, 120

min, or the moon pool, 90 min) in this ArcticNet/CFL cruise. The figure 1 gives an example of the expected results.

Sampling

In total, 66 profiles have been taken with the SCAMP and 100 with the VMP in 27 different stations. The table below shows the details of this sampling.

SATATION	DATE	LOCATION	LAT	LON	MEASURE
101	29-SEP-07	Baffin Bay	76.2675	-77.26669	SCAMP
101	30-SEP-07	Baffin Bay	76.2997	-77.2294	VMP
105	30-SEP-07	Baffin Bay	76.1902	-75.3268	VMP
115	01-OCT-07	Baffin Bay	76.2212	-71.19	SCAMP
111	02-OCT-07	Baffin Bay	76.1801	-73.0684	VMP
108	03-OCT-07	Baffin Bay	76.1364	-74.4094	SCAMP
108	03-OCT-07	Baffin Bay	76.1309	-74.5035	VMP
302	07-OCT-07	North-West Passage	74.0899	-86.1330	SCAMP
308	09-OCT-07	North-West Passage	74.0792	-103.0791	SCAMP
308	09-OCT-07	North-West Passage	74.0744	-103.0284	VMP
309	10-OCT-07	North-West Passage	74.40127	-103.07749	VMP

2.3. Team 2

2.3.1. Ice dynamics

PI: David Barber
Participants: Monika Pucko, Phil B.J. Hwang, Pascale Collin, Mukesh Gupta, Dan Leitch (all at CEOS, University of Manitoba)

Ice physical-microstructure (Ice Raid)
Monika Pucko, Phil Hwang & Pascale Collin

General ice conditions:
During Leg 3B we encountered pancake ice very frequently. This large number of pancake ice is likely due to strong south-eastern wind which prevailed during most of the period in Leg 3B. As air temperature quickly decreased to about -20°C on Nov. 3, we frequently encountered frost flowers on the bare ice surface.

Physical sampling:
A field program (Ice Raid) was designed to obtain the physical-microstructure properties of snow/sea ice. To access the ice surface during Leg 3B, we used ice cage (see Figure 1.1), lowered from the starboard side of the ship. Air and ice temperatures were measured by a hand-held temperature probe (Traceable, Digital Thermometer, 4000C).

Ice surface condition (i.e., snow, frost flower or slushy layer) was recorded. In case of slushy layer, we scraped the surface slushy layer and put the scarped sample into a whirlpak bag for the salinity measurement. We also measured the thickness of the slushy layer if it is thick enough. In case of frost flower, the standard procedure are 1) to take the photos of frost flowers using a digital camera (Pentax, Potio W30) mounted on a purpose-made camera stand to estimate spatial coverage of frost flower, 2) and to take micro-scale photos of frost flowers with macro setting. We described the presence of slushy layer underneath frost flowers. In case of snow, we measured the snow depth and described the characteristics of snow (i.e., the presence of slushy layer), and also took some pictures of snow. Standard procedure also includes taking photos of snow grain size and capacitance (snow wetness) measurements. Two ice cores were taken: one for microstructure analysis and the other for salinity measurements. To measure bulk ice salinity we cut an ice core into several pieces for 2.5 - 5 cm interval and put the ice piece in a waterproof bag until it's melting. We recorded conductivity, temperature and salinity from a conductivity meter.

We set up the cold lab (-20°C) to take ice microstructure photography: thick and thin sections (see Figure 1.2). The temperature of the cold lab varied between -15°C and -20°C, but occasionally increased up to -8.0°C. The crew fixed the problem around Nov. 3. Since then the temperature of the cold lab was constant around -20°C. To take thick section photography, we cut an ice core into pieces and attached the piece on a glass plate, and fixed the ice piece by applying three layers of freshwater around the piece. Once, the ice piece firmly fixed on the plate, we prepared a thick section by shaving down the ice piece to about 5-10 mm thick. Then, we took pictures of the thick section by a digital camera (Canon, PowerShot G2) to see air bubble or brine pocket/tube distribution. A stereomicroscopy may be used to see more detailed distribution of air bubble or brine inclusions in a higher resolution. Once thick section pictures were taken, we shaved down the ice piece to a few millimeter thick (called a thin section). Then, we took cross- and parallel-polarization images from the

thin section by putting polarized sheets under the ice section and between the ice section and the digital camera.

Total 14 ice samples were collected for physical-microstructure analysis (Table 1.1). Ice thickness varied between 5 cm and 30.5 cm, and the ice samples included nilas, consolidated pancake and grey ice.

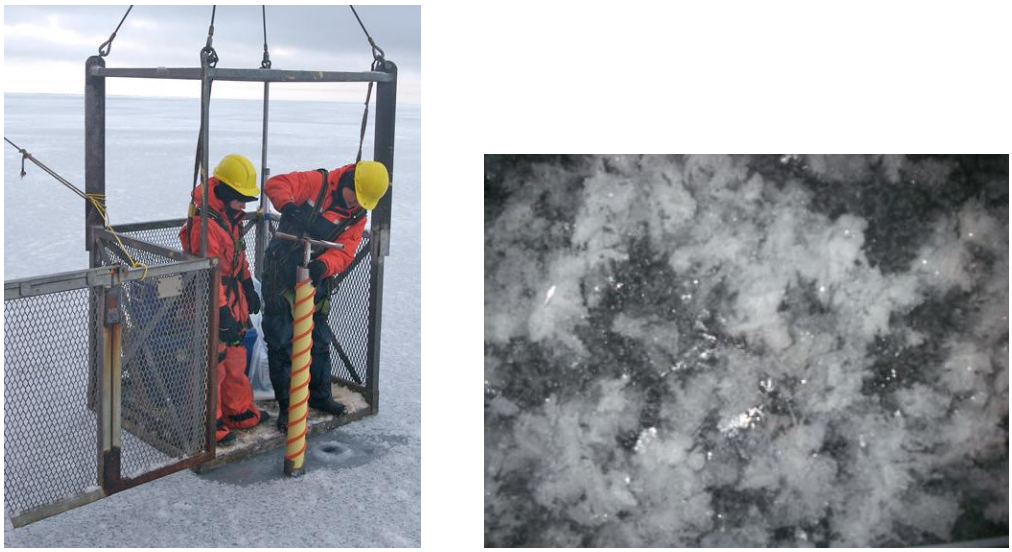

Figure 1.1 Ice cage (left) used for "Ice Raid" to obtain the physical-microstructure properties of snow/sea ice, and a picture of frost flowers (right) during ice raid on Nov. 6.

Surface EM measurements

Mukesh Gupta & Phil Hwang

Objectives:

Ship-based ice-EM measurements were conducted to investigate the interactions between microwave signatures (both active and passive) and sea ice thermophysical properties. The observed data will be used to calibrate sea-ice products from the satellite sensors and to evaluate the theoretical microwave emission/scattering models. This result will provide more advanced knowledge of how microwave signature reacts to the evolution of sea ice thermo-physical properties on small scales during the fall freeze-up period.

Instrumentation and methods:

The radiometers are dual polarized (vertical and horizontal) radiometers at 37 and 89 GHz with 6° beamwidth antennas (Radiometrics). The radiometers were mounted about 12 m above the sea surface on the portside of the ship (Figure 2.1). During transect, the radiometers were fixed at the incident angle of 55°. Whenever the ship was stationary, we changed the incident angle of the radiometers from 30° to 150° at a 5° interval. A network camera (Canon, VB-C10R) was mounted on a rail right beside the wheelhouse. The initial set-up for the camera was pan=0.00°, tilt=-25.00° and zoom=43.40° and was changed to tilt=-40.00° from Nov. 1. The pictures were taken every 10 seconds to 1 minutes depending on surface conditions. A hand-held digital camera was also used to record the visual surface condition.

A C-band polarmetric (VV, VH, HV, HH) scattereometer system (PROSENSING) was deployed about 7.56 m above the sea surface (Figure 2.1). Whenever the ship was stationary, measurements from the ship were done from -30° to 30° in the azimuth, with the 0° reference at a perpendicular line to the ship side and from 20° to 60° in elevation at 5° increment. An infrared transducer (Everest, 4000L) was mounted on a rail in the shed for the C-band scattereometer system (Figure 2.1). Ice thickness camera was set up on the main deck at the port side.

We investigated the feasibility of Laser Wave Slope (LAWAS) in estimating sea ice surface roughness in collaboration with Sara Woods.

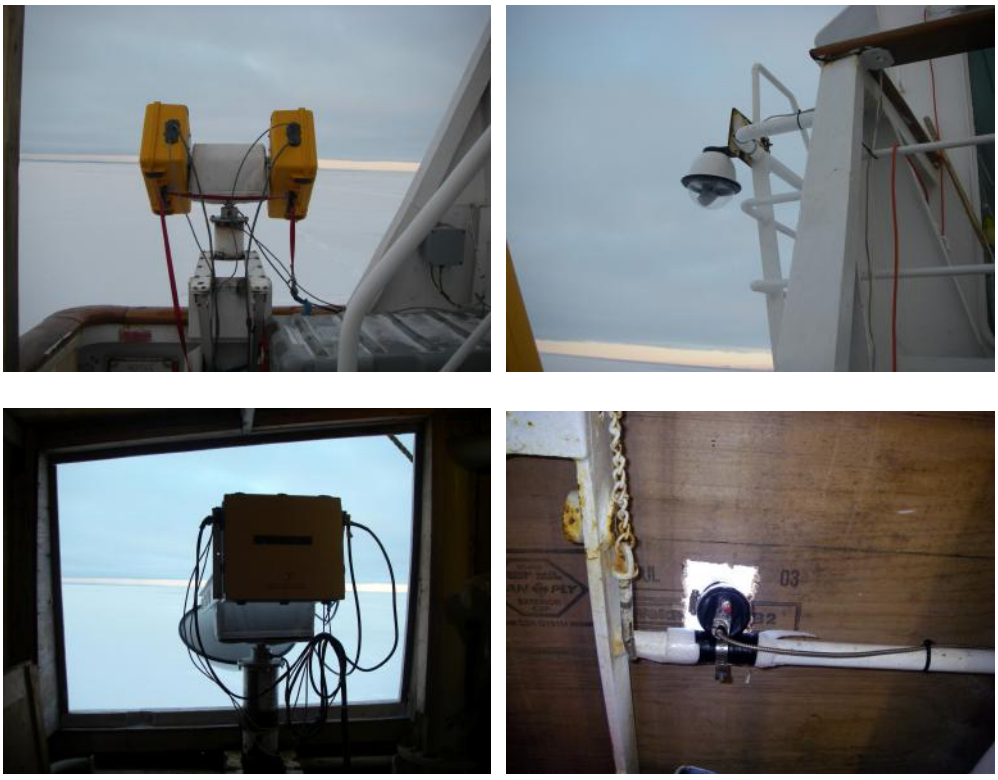

Figure 2.1 Microwave radiometer system (top left), webcam (top right), scattereometer (bottom left) and infrared transducer (bottom right).

Color dissolved organic matter (CDOM), fluorescence of dissolved organic matter (FDOM), salinity and oxygen isotope ($\delta^{18}O$)

Pascale Collin & Dan Leitch

Water and ice were collected onboard using the rosette and the ice cage at selected stations (see Table 1.1 and 3.1). The water was collected at 0 m, 5 m, 10 m, 25 m, 50 m, 100 m and 200 m on contaminant casts. The surface samples were always collected using a bucket during the rosette cast on the forward deck. $\delta^{18}O$ was collected by team 5 during basic and full station on the rosette at depth 0 m, 5 m, 7.5 m, 10 m, 25 m, 50 m, 100 m, 200 m and bottom.

The surface water was collected directly on the ice by scooping the surface with a bottle for each ice station. The CDOM and FDOM sample were collected at selected stations. For the ice station selected for CDOM and FDOM analysis, $\delta^{18}O$, HCH, salinity has been collected, physical properties of sea ice has been noted and vertical microstructure analysis of the ice has been processed. Due to problems with the spectrophotometer Cary 50, the CDOM samples has been store at $4^{o}C$ and measurements of CDOM will be completed at University of Manitoba.

Preliminary Results:

CDOM and FDOM analysis will be performed after the cruise in laboratories at the University of Manitoba. Stable isotope analysis of water and ice samples will be analyze outside of the university.

Hexachlorocyclohexanes (HCHs) concentration and enantiomeric composition in the sea ice

Monika Pucko

Ice samples for HCHs concentration and enantiomeric composition were collected at each basic and full station where the newly formed ice was present (except from 30th of October 2007). The samples for oxygen isotope composition ($\delta^{18}O$) and salinity were taken along with all ice samples. The ice samples were collected in collaboration with team 8 (Gary Stern, contaminants) in order to link HCHs

concentration and chiral composition in different parts of the environment with the Arctic climate changes (see team 8 cruise report). In cases where more than one type of ice was present, 2 ice samples were collected. The total of 12 samples of newly formed sea ice for HCH analysis was collected (see Table 1.1 and 3.1).

Ice samples for HCH analysis were collected from the ice cage [refer to Section 1. Ice physical-microstructure (Ice Raid)]. When the ice was thin enough, the ice chipper was used. In case of thicker ice (>15 cm) the ice cores were taken. The total of 4-8 L of melted ice was pumped through a glass-fiber filter followed by an ENV+ solid-phase extraction (SPE) cartridge using peristaltic pumps. The cartridges and GFFs were stored in -80 °C and brought to the DFO (Winnipeg) for further chemical analysis.

Logistics:

Recommendations:
The temperature of the cold room (lab 555) and the refrigerated room (lab 554) **needs to be verified more often and constantly**. **The temperatures of both labs are fluctuating with the change of air temperature outside.** A periodic reading could be done e.g each 2 hours. A log sheet should be posted outside of the labs with the time and temperature reading and the initials of the person responsible of the readings. We need to insure the constancy of the temperature to avoid samples to melt or to be in improper storage temperature.

2.3.2. Canadian Arctic Buoy Program

PI: Bruno Tremblay
Participants: Jean-François Lemieux & Bruno Tremblay

Funded by: Canadian Foundation for Innovation - McGill Excellence fund from the Faculty of Science and matching funds from the department of Atmospheric and Oceanic Sciences at McGill.

The Canadian Arctic Archipelago (CAA) is expected to become navigable in the near future. Current estimates are based on simulation results from General Circulation Models (GCMs). The spatial resolution of GCMs, however, only allows for a coarse representation of the CAA. To this end, higher resolution models are needed in order to better predict the future evolution of the sea ice in the CAA. Until now, sea-ice dynamic models have been calibrated against buoy drift data in the Arctic Ocean from the International Arctic Buoy Program (IABP) - IABP has no buoys deployed in the CAA. Whether the calibration of these models and the continuum assumption upon which they are based, are still valid at high resolution remain an open question. To address this, we propose to make in-situ measurements within the narrow passages of the CAA. In particular, we will monitor the temporal evolution of sea-ice deformations, internal ice stress and ice thickness. These measurements will be used to calibrate/validate a high resolution sea-ice model that is being developed in our group. The sea-ice model is based on the granular material rheology (Tremblay and Mysak, 1997). The dynamical part of the model is now solved using the Generalized Minimum Residual method (GMRES), with a line Successive Overrelaxation (LSOR) preconditioner. This new implementation constitutes a significant improvement in numerical efficiency and allows for the integration of the model at high resolution over a domain including both the CAA and the Arctic Ocean.

We will deploy 3 ice buoys each year for 3 years in the M'Clintock or the Viscount-Melville Channels within the CAA. The buoys are manufactured by METOCEAN (Dartmouth, Nova Scotia). They are tested and pre-programmed in house prior to deployment. Three types of buoys will be used: a Spherical Drifter (SVP), an Ice Stress Buoy (ISB), and an Ice Mass Balance Buoy (IMBB). The SVP includes a Global Positioning System (GPS) and an Iridium transmitter. The ISB includes a Campbell scientific data-logger, a Global Positioning System (GPS), an ARGOS transmitter, 2-meter barometric pressure and surface air temperature, and a set of Geokon strain gauges for sea-ice stress measurements. The IMBB include a GPS, a Campbell scientific data-logger, a Global Positioning System (GPS), an ARGOS transmitter, 2-meter barometric pressure and surface air temperature, a thermistor string within sea ice, and above-ice and below-ice acoustic sounders measuring the height of the surface and bottom.

During Leg 3A we successfully deployed three SVP and 1 IMBB and are presently transmitting data via Iridium and ARGOS – this data is available online upon request. This year the ISB was not deployed - the buoy is currently in development at METOCEAN and will be deployed starting next year. A third SVP was deployed instead. The buoys were deployed using the logistic support of the *CCGS Amundsen* and its helicopter. The proposed buoy arrangement will allow the direct measurement of sea-ice thermodynamic growth/melt (using the IMBB), growth through sea-ice convergence (ridging) by monitoring the changes in area enclosed by the three buoys, sea-ice mechanical properties (using the internal ice stress measurements from the ISB, together with a knowledge of the wind forcing from local weather stations and reanalysis data), and sea-ice deformation using the stress and strain-rate information for the set of three buoys. The life expectancy of a buoy is approximately 2 years. The 3-year buoy deployment effort will therefore provide four years of data. This data will feed into a longer-term modeling effort by the PI who is working together with PhD students and postdocs on the validation of the high resolution sea-ice model of the Canadian Arctic Archipelago (including the Arctic Ocean).

Currently, sea-ice drift data from the CAA are quasi non-existent. The IABP focuses mainly on the Arctic Ocean, and of its 39 presently active buoys, one is located at the mouth of the Nares Strait

(between Greenland and Ellesmere Island), and one at the mouth of the Lancaster Sound. Also, sea-ice drift estimates from passive microwave imagery SSM/I are not possible in the CAA due to the small deformations present over the usual 3-day swath period. Our buoy deployment effort will complement the IABP. The Buoys also provide surface air temperature and pressure. These data are being assimilated in reanalysis products and weather prediction models such as National Centers for Environmental Prediction - National Center for Atmospheric Research, and European Center for Medium-Range Weather Forecasts. The calibration/development of the high resolution model for this region will give us a unique opportunity to address questions such at the timing of the opening of the North-West Passage to navigation, and the future of the sea-ice cover in the CAA in a warming world. This is crucial for Canada for the management of its interior waters and economic planning/development of the High Arctic.

2.4. Team 3

2.4.1. Remote sensing

PI: Pierre Larouche (DFO-IML)
Participant: Sélima Ben Mustapha (Université de Sherbrooke)

Rationale:
To understand and to monitor biophysical processes in complex coastal waters it is necessary to use remote sensing methods. CASES measurements showed that optical properties of the Beaufort Sea and the Amundsen Gulf region are dominated by the freshwater outflow from the Mackenzie River leading to a bias in the estimation of phytoplankton biomass using remote sensing data. There is thus a need to develop specific methods to make more effective use of remote sensing data. The building of a database of inherent optical properties relating a wide variety of physical and biological conditions is a crucial step towards this goal.

Objectives:
The general objective of our team is to study the relationship between the spatial and temporal distribution of the phytoplankton and the physical environment in the Canadian Arctic with an emphasis on the Beaufort Sea and the Baffin Sea using remote sensing data.

Specific objectives for the Arcticnet/CFL 2007-08 cruise are:

- The estimation of the ability of current bio-optical algorithms to measure chlorophyll-a concentration;
- The development of specific algorithms for a variety of ocean color sensors which will in turn provide a better understanding of the Beaufort Sea and the Baffin Sea physical and biological processes;
- The analysis of light absorption properties of arctic phytoplankton.

To reach these objectives, we will measure the following parameters:

(1) the transparency of the water with a Secchi disk;
(2) profiles of light in the water column with a Profiler of Natural Fluorescence (PNF 300);
(3) the pigment composition of phytoplankton with the high performance liquid chromatography method (HPLC);
(4) the algal pigments;
(5) the total suspended matter;
(6) the chromophoric dissolved organic matter (CDOM).

Methods:
Light profiles in the water column were done with a PNF-300 and we measured the water transparency with a Secchi disk at every station to determine the photic depths, except for some stations that were sampled during the night.

Water samples were taken at each station using Niskin bottles attached on the CTD rosette system. Samples were taken at 6 photic depths corresponding to 100%, 50%, 10%, 1% light levels, at the chlorophyll maximum as determined from the downcast fluorometer profile and at 60 metres to provide reference data under the pycnocline.

Filtrations were performed for chlorophyll determination (HPLC techniques), a_{ph}, total suspended matter (TSM) and chromophoric dissolved organic materiel (CDOM).

Surface water was collected using a clean bucket at all stations. Sub-samples were immediately collected to measure CDOM, chlorophyll-a, algal pigments and suspended matter concentrations.

For chlorophyll-a, and algal pigments, water samples were filtered through 25 mm GF/F filters, flash freezed and stored in liquid nitrogen on the ship. Samples will be transported south for analysis at the end of the leg.

CDOM samples were filtered using 0.2 µm Anotop® syringe filters (Whatman) and collected into 60 ml acid-cleaned amber glass bottles. The bottles were stored frozen (-20 ˚C) in the dark on the ship. Samples will be transported south for analysis at the end of the leg.

Total suspended matter was measured by filtering up to 2 litres of water using pre-weighted 25 mm GF/F filters. The filters were stored on the ship at –80 ˚C, to arrest pigment degradation (Sosik, 1999), and will be transported south at the end of the leg to complete the analysis.

Detailed sampling activities are summarized in the Appendix.

Conclusion:
The Arcticnet / CFL LEG3 operations were successfully completed between September 27 and November 8, 2007. This was a successful cruise with more samples gathered than previously planned.
We have 33 Stations with a total of 617 samples.
The chief scientist was comprehensive of the particular needs of the optics team, and the captain and crew members were professional and cooperative for scientific operations.

Remarks:
At the beginning of the cruise, it was planned to process CDOM samples [$a_{CDOM}(\square)$] on board using a Cary 50 spectrophotometer. Unfortunately that piece of equipment broke between legs 1 and 3 forcing us to store the samples and bring them back at the end of the leg. Obviously, this is not the best strategy as the effect of a long storage on data quality is not known and as this puts additional pressure on the already limited airplane capacity. A solution must be found to bring a replacement spectrophotometer on board to measure samples of CDOM in future legs.

We recommend finding best ways to transport samples at the end of legs.

Acknowledgements:
We thank the captain and the crew of the CCGS Amundsen for enthusiastic and professional assistance on board. We are particularly indebted to the crew members who helped with some operations.We are grateful to the scientific chief, Jean-Éric Tremblay, for his devotion and professional work during the expedition.

2.5. Team 4

2.5.1. Zooplankton, fish, acoustics & moored Sediment Traps

PIs: Louis Fortier (Laval University), Yvan Simard (ISMER) & Jacques Gagné (DFO – IML)
Participants: Alexandre Forest, Keith Lévesque, Louis Létourneau (all at Laval University), Jacques Gagné and Yvan Simard, with the help of Joanne Delaronde & Alisson MacHutchon (DFO-FWI), Luc Michaud, Pascal Massot & Steve Gagné (Laval)

General objective and field program
The general objective of our team is related to the overarching goal of ArcticNet project 1.4 led by Professor J.-É. Tremblay (U. Laval) 'Marine productivity and sustained exploitation of emerging fisheries' which is to assess the impact of sea-ice cover reduction and increasing sea temperatures on biological productivity, fisheries resources and marine mammal populations of the coastal Canadian Arctic. This assessment aims to document and anticipate the present and future biodiversity/availability of marine renewable resources, and to propose management strategies for a sustainable exploitation. Aboard the *CCGS Amundsen*, we collect key indices of the ecosystem maturity at the end of the biological production season (September to November) and we re-deploy automated instruments that record all year-long the vertical flux of biogenic matter and marine mammal distribution. The ArcticNet-CFL 2007 (leg 3) expedition consisted thus mainly of a monitoring cruise following the previous ArcticNet 2005 and 2006 cruises.

However, the 2007 cruise differed from the previous missions, since it is a component of the 15-months Amundsen's expedition as part of Canada's contribution to the International Polar Year (IPY) 2007-2008. In particular, the second half of leg 3 (18 October – 8 November) was the beginning of the Circumpolar Flaw Lead System Study (CFL) which will examine on an annual cycle how the physical processes moderate biogeochemical processes within the changing northern flaw lead ecosystem nearby Banks Island (Beaufort Sea). Therefore, the sampling during this period can be seen as a pre-winter survey of the flaw lead area to get an indication of the status of the marine ecosystem at the end of the growth season and associated physical forcing. Our multidisciplinary ArcticNet team

is thus strongly linked with Team 4 (Pelagic and Benthic Foodwebs – Fortier) and Team 7 (Carbon Fluxes – Tremblay) of the CFL program.

Operations during the ArcticNet-CFL leg 3 were spread on the East-West gradient of the Canadian Arctic. This represented a large spectrum of sampling conditions and three oceanographic regions were visited: 1) the NOW polynya of Baffin Bay (Eastern Arctic), 2) the Northwest (NW) Passage, including opportunistic sampling nearby Nanissivik, and 3) the south-eastern Beaufort Sea (Western Arctic) comprised of the Mackenzie and Banks Shelves, and of the Amundsen Gulf area (the CFL study region).

The main field objectives of our multitask ArcticNet Theme 1.4 sub-team were:
1) To assess zooplankton / fish abundance and diversity by using various plankton nets.
2) To track zooplankton / fish biomass and distribution with the EK60 Echosounder.
3) To turnover the automated sediment traps and hydrophones deployed on the moorings.

In addition, zooplankton samples collected during leg 3 are also of use in other ArcticNet-CFL subprojects such as the cycling of contaminants (G. Stern). As well, part of the samples collected will be used in a study to identify the sources and pathways of omega-3 in the arctic marine food chain (J. Michaud, E. Dewaily and L. Fortier) and is linked to the ArcticNet theme 1.5 that is focussing on the importance of omega-3 fatty acid in the traditional diet of Inuit communities. Also as part of the CFL Team 4 on the pelagic food web, the assessment of the respiration rates of the zooplankton community by the Electron Transfer System (ETS) activity method was performed at chosen stations (G. Darnis and L. Fortier). At some stations, zooplankton samples were also collected for genetic studies at Woods Hole Oceanographic Institution (Victoria Starczak) and at UQAR (France Dufresne and Adriana Radulovici).

In total, 32 stations were visited for zooplankton & fish sampling. However, the ice conditions (multiyear ice floes or fast-growing sea ice) severely constrained the sampling at many stations during leg 3. Acoustics EK60 monitoring was done continuously during the whole cruise. On the moorings, 1 automated sediment trap was recovered (CA-18C) and 9 were deployed (in Beaufort Sea only). The Table 1 (p. 3) summarizes the sampling activities at each of the 32 stations. And the details of the operations are fully described in the following sections: 1- Zooplankton & fish sampling (p. 4); 2- Acoustic monitoring (p. 7); 3- Mooring operations (p. 9).

Zooplankton & Fish Sampling

a) Vertical tows (4X1m^2- Monster Net, Hydrobios)

4x1-m^2 Square (Monster Net, Figure 2a): Frame rigged with four square 1m^2 opening nets (3 x 200, 2 x 500 µm mesh), out-rigged with a 10 cm diameter net (50 µm) and equipped with flowmeters (2 GOs and 2 TSKs). These nets were used for integrated water column sampling. When deploying, winch speed down was <30 m/min to avoid mixing of the nets, and winch speed up was 40m/min. The content of one 200 µm (TSK-QT) and the 50 µm mesh-net were preserved in formaldehyde for taxonomy (Fortier). The content of the three other nets were sorted for contaminants, lipids and genetics studies. At some stations, ETS assays were performed using one of the integrated tows (see Table 2 for details). This gear was systematically deployed at all basic and full stations.

Hydrobios Multi plankton sampler (Figure 2b) equipped with nine 200 µm-mesh nets (opening 0.5 m^2). This was allowing for depth specific sampling of the water column. The *Hydrobios* is also equipped with a CTD to record water column properties while collecting biological samples. When deploying, winch speeds down and up were both 40m/min. The *Hydrobios* was deployed at full stations in every region when conditions were favourable. At some stations, the content of each net was divided between preservations (4% buffered formaldehyde) and ETS assays were performed (see Table 2 for details). Please note that the recurrent problem with the *Hydrobios*'s flowmeters has not been resolved yet (they do not work in the water, while they work on deck).

Table 2: Details of the ETS/biomass assays performed during leg 3

			Vertical profiles (Hydrobios)		Integrated (Monster Net)		Stage-specific (Monster Net)	INT solution (#)
Date	Station	Sampling	ETS	Biomass	ETS	Biomass	ETS

26-Oct	1000	350 - 0 m			X	X	X	2
27-Oct	1100	240 - 0 m			X	X		2
28-Oct	1116	220 - 0 m	X	X				2
31-Oct	1200	190 - 0 m			X	X		2

b) Oblique tows (Tucker, RMT and Trawl)

Double 1-m^2 (Tucker Net, Figure 2c): Type gear rigged with two 1m^2-opening nets (500 µm mesh each), out-trigged with a 10 cm diameter net (50 µm mesh) and equipped with flowmeters (1 GO & 1 TSK) and a temperature-depth recorded (TDR). When towed, ship speed was 2-2.5 knots and winch speed down was around 30 m/min and around 20m/min on the way up. This gear was mainly use to catch fish larvae (see Figure 1 for details of the catches) and to provide water column zooplankton samples from the upper 100 m layer. One of the 500 µm mesh net was preserved in 4% buffered formaldehyde for taxonomy and the other 500 µm mesh met was sorted for contaminants, lipid and genetics studies. This gear was deployed at both basic and full stations when ice conditions were favourable.

RMT: Rectangular Mid-water Trawl (Figure 2d) of an opening of 9 m^2 fitted with a 1600 µm mesh-net and equipped with a flowmeter and a TDR. When towed, ship speed was typically 2-3 knots; and winch speed down was 30 m/min and around 20m/min on the way up. This net, only deployed at full stations (ice dependent), was used to catch larval and juvenile fish (see Figure 1 for details). Collected zooplankton was equally divided for taxonomic and contaminant studies.

Trawl: Experimental Mid-water Trawl (Figure 2e) fitted with multiple mesh size; flexible mouth opening; depth, fish counting & aperture probes; tried to be used to catch adult fish. (validation of the EK-60 echosounder). The pelagic trawl was deployed once at an opportunistic location nearby Nanissivik (Lancaster Sound). No adult fish were caught but several juvenile Arctic Cod (~250) got caught by the trawl (see next section for details).

Figure 1: Summary of the young fish catches (larvae & juvenile) during ArcticNet-CFL leg 3: (a) total number of fish; (b) length classes of Arctic cod (*Boreogadus saida*)

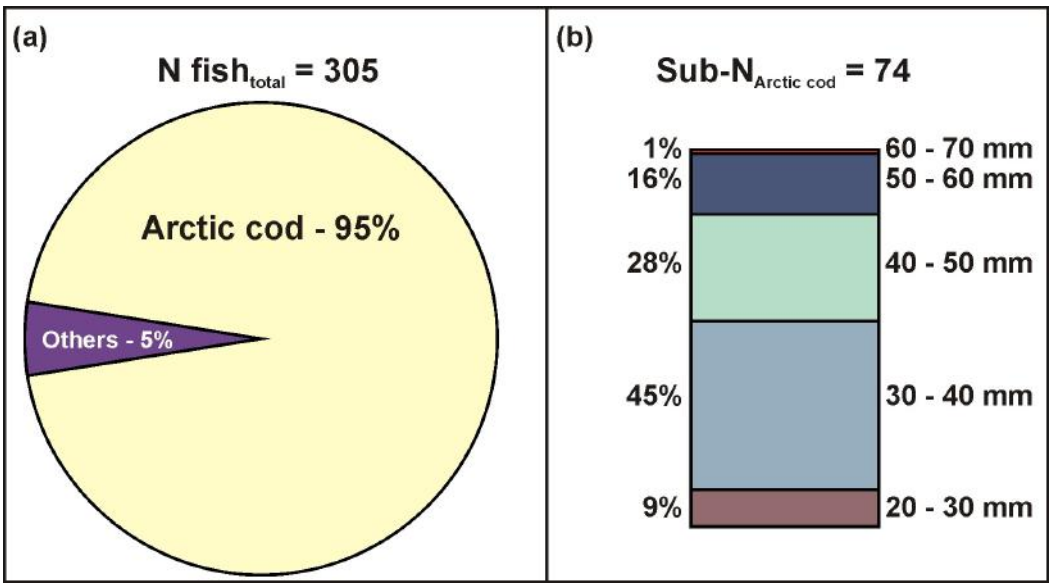

Figure 2: The different instruments used to sample zooplankton & young fish during leg 3

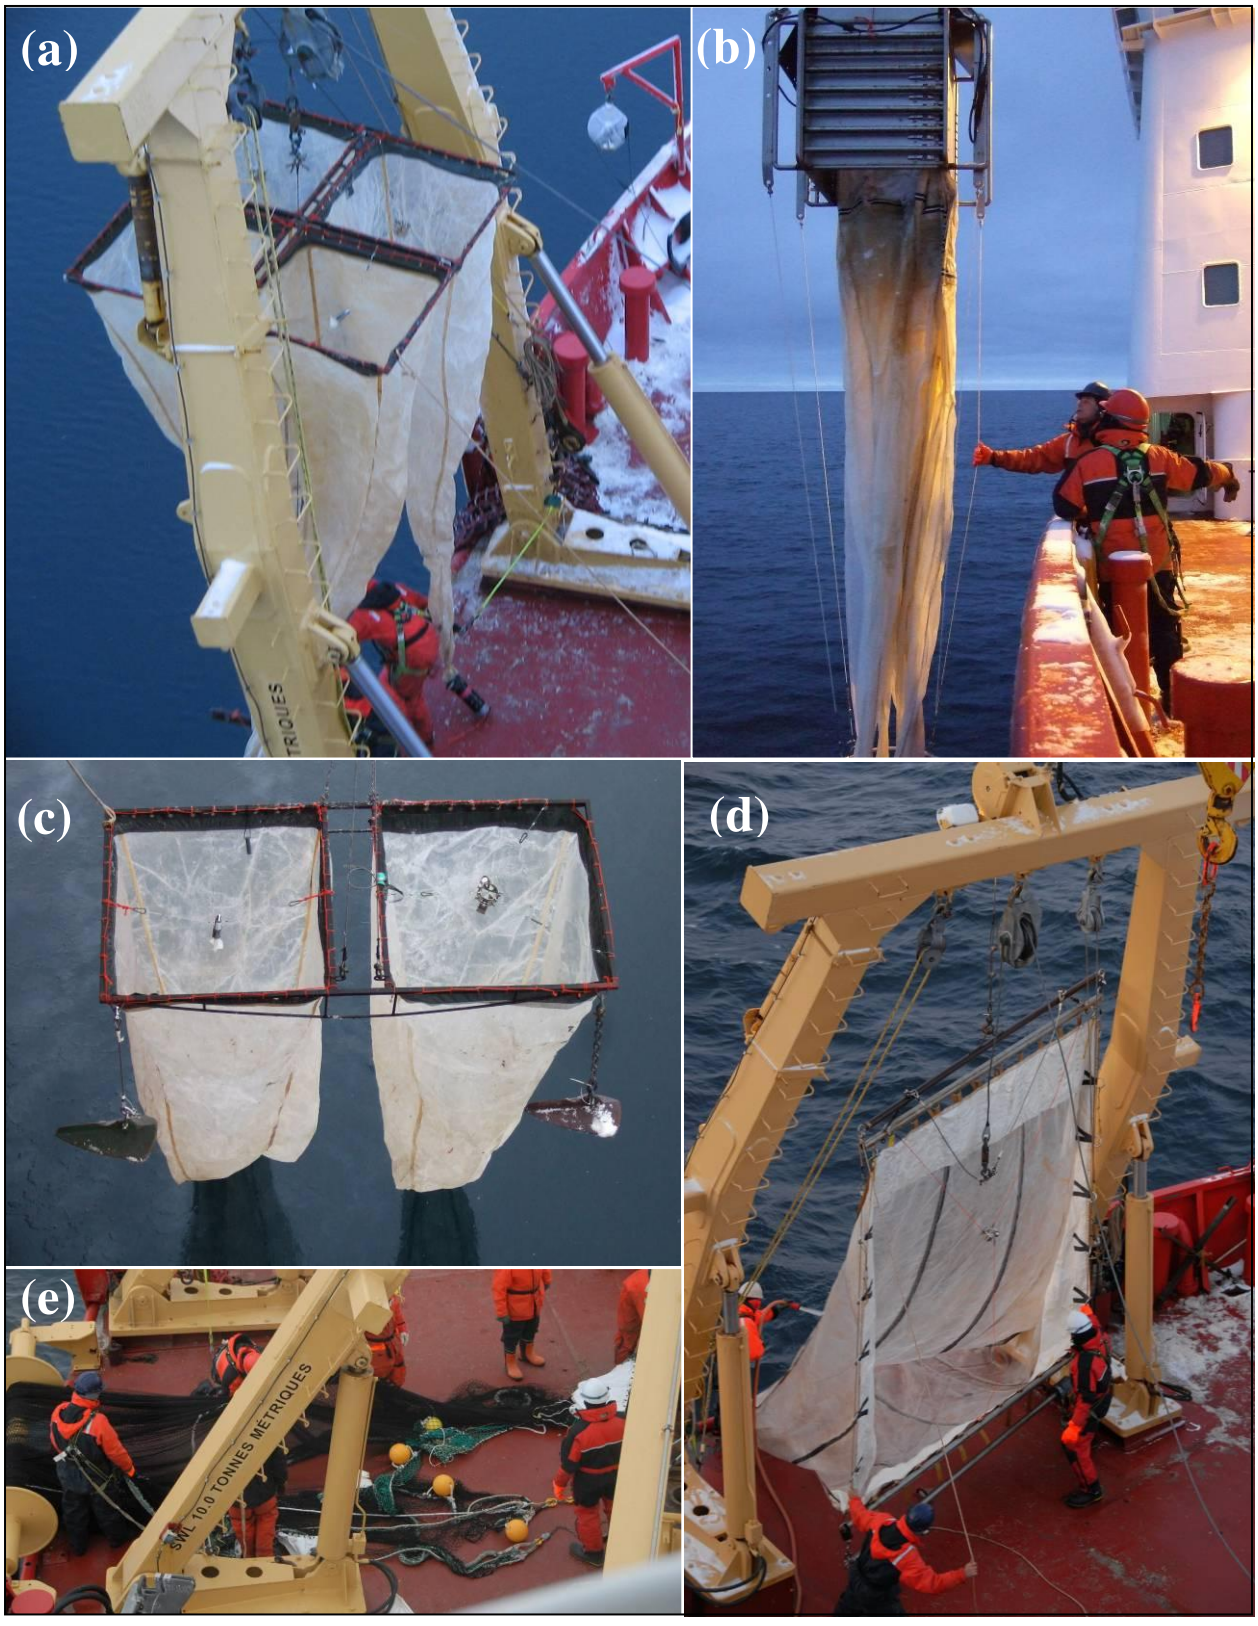
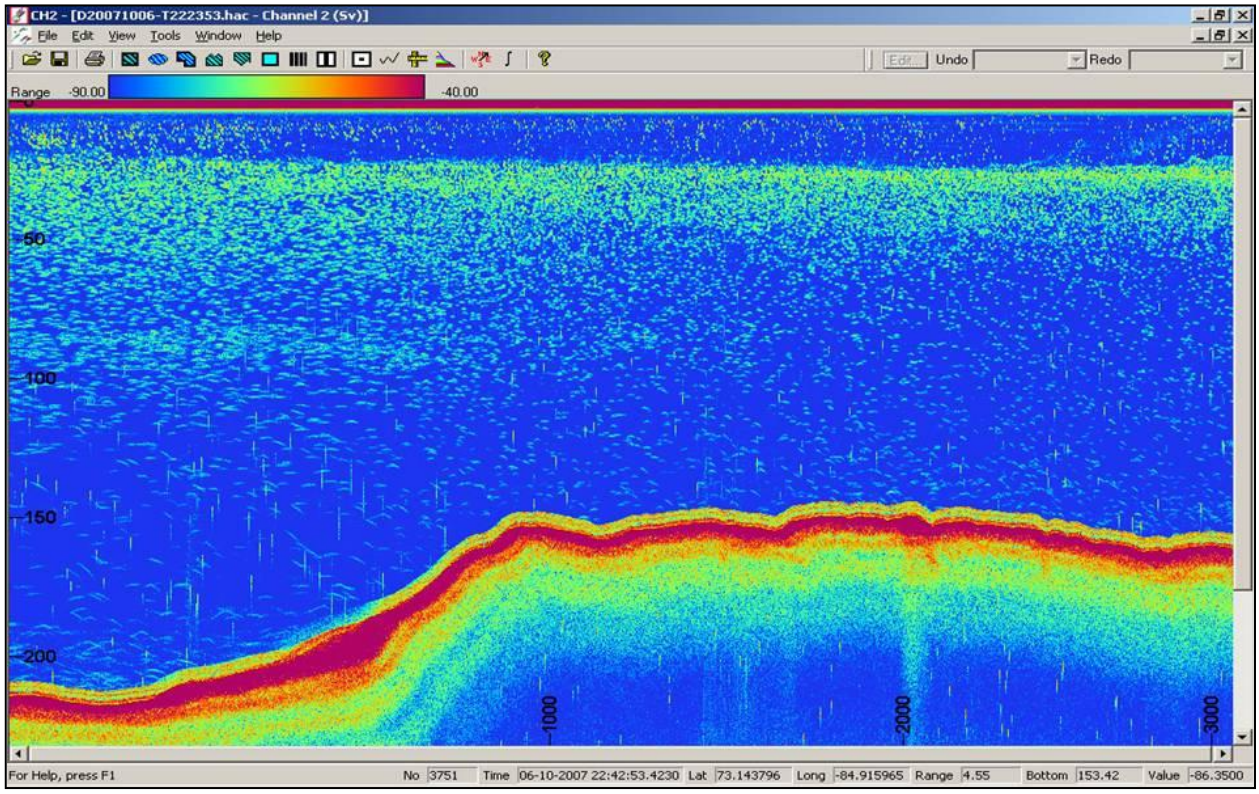


The Amundsen is equipped with a scientific echosounder, the EK-60, to continuously monitor the distribution of zooplankton and fish. A particular attention is devoted to Arctic cod, *Boreogadus saida*, which plays a key role in the Arctic marine ecosystem. During the first part of leg 3, an acoustic layer was detected between 20 and 100 m below the surface (Figure 3) everywhere along the route of the vessel from Resolute to the Greenland coast. Based on the analysis of the split-beam information, it seemed to contain mostly small fish and large zooplankton. When comparing the vertical distribution of the echoes to that of the water column characteristics obtained from Rosette casts, the acoustic layer appears to be associated with an intrusion of warmer waters below the surface. Another acoustic layer likely resulting from the presence of larger fish and associated with different water mass was present between 250 and 500 m. This layer, which according to its multifrequency acoustic signature also contains zooplankton, was more concentrated in the western part of Lancaster Sound. It settled on the bottom of the NOW polynya around the 350 m depth contour, especially on the Canadian side.

Figure 3: Typical EK-60 feature in Eastern Arctic (taken nearby Nanissivik, 6 Oct-2007)



An experimental pelagic trawl is also available on the Amundsen to sample concentrations of juvenile and adult fish for ecological studies and EK-60 echo validation. This trawl was deployed on October 6 off Nanisivik in the upper acoustic layer between 25 and 50 m. The catch consisted mainly of small Arctic cod about 4-5 cm long and large amphipods (Figure 4), confirming our interpretation of the echograms based on the TS (Target Strength) – size relation published by Crawford and Jorgenson (1996) for *B. saida*. It thus appears that juvenile Actic cod might represent the main source of this extensive epipelagic layer detected also during previous ArcticNet surveys. Juveniles of that key prey species could therefore be widely distributed slightly below the surface over immense expenses of the eastern Arctic Ocean, at least at this time of the year, in association with specific water masses.

Figure 4: The catch of Nanissivik

Zooplankton and fish biomasses were much less important west and south of Lancaster Sound based on the acoustic records for the Eastern entrance of Melville Sound and from M^{c}Clintock Channel to Queen Maud Gulf. They increased in Coronation Gulf to reach high values again through to the Amundsen Gulf. Based on the analysis of the EK-60 data obtained during previous ArcticNet surveys, this area and the Lancaster Sound – Baffin Bay region had been identified as *hot spots* for the sampling of juvenile and adult Arctic cod. Unfortunately, we could not deploy the pelagic trawl again because of logistic and operational constraints. Biomasses returned to a low level in the Beaufort Sea survey area.

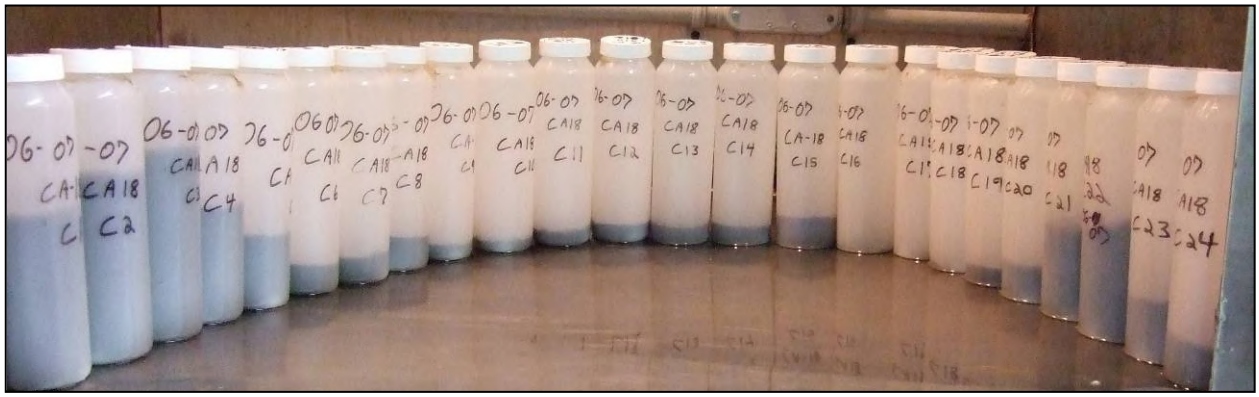
Mooring operations

The automated sediment traps installed on the moorings collect sequentially over the year the vertical flux of sinking particles (e.g. senescent plankton, excrements and detritus). The characterization of the vertical particle flux is key information to understand the marine ecosystem dynamics and the impact of environmental changes. By example, the magnitude of the flux's biogenic component (the organic fraction) is directly linked to the surface biological production and food web activities. In coastal shelf areas (such as Beaufort Sea), the collection of sinking particles serves also to estimate the input of terrigenous material (the inorganic fraction) into the Arctic Ocean. Both biological production and terrigenous inputs are expected to increase as sea ice reduces and temperature increases in the Arctic. The consequences of these environmental changes on the food web and carbon cycling are unknown. Hence, the sediment trap deployments are a crucial element of the ArcticNet monitoring science program that aims to establish a long-term series of marine observatories in the Canadian Arctic.

The mooring program suffered from a **very** serious drawdown during the leg 3 of ArcticNet-CFL 2007. We did not recover any of the two mooring deployed in Baffin Bay in 2006; and we recovered only the lower third of CA-18, one the three moorings deployed last year in Beaufort Sea. As a result, we retrieved only one sequential sediment trap out of the 11 traps deployed in these two regions

during the ArcticNet 2006 expedition (Figure 5 and 6a). In both regions, the primary problem seemed to be the ice cover that hit the moorings (icebergs or thick sea ice). A second hypothesis is that the batteries of the acoustic releasers experienced a major technical failure. For a complete report on the mooring problems and the way they were faced, we refer the reader to the official report by Senior Mooring Technician Mister Luc Michaud (SMTMLM).

Figure 5: The single sediment trap time-series retrieved during leg 3 (from CA-18, 490m)



On the other hand, the pool of mooring equipment provided by the new CFI grant allowed us to maintain the marine observatories in Beaufort Sea as part of the CFL-IPY overwintering program. The 5 planned moorings equipped with sediment traps were therefore deployed in Beaufort Sea as scheduled (as the two planned MMP moorings). However, we did not deploy any moorings/sediment traps in Baffin Bay this year. As a result of the sediment trap shortage, we also decided to deploy the trap that was reserved for an under-ice experimental time-series in spring 2008 as part of the CFL study. Thus, we deployed all the new Technicap PPS-3/3-24cups that were brought onboard the CCGS Amundsen (e.g. Figure 6b). The Table 3 presents a summary of the recovery/deployments performed during ArcticNet-CFL leg 3.

Table 3: Summary of the recovery/deployments of moored sediment traps during leg 3

Date	Mooring	Operation	Latitude	Longitude	Sediment trap	Depth
18-Oct	CA-04	Deployment	71° 04.842' N	133° 37.97' W	Technicap PPS 3/3-24	112 m

2.5.2. Sediment and benthos

PIs: Archambault, P. (ISMER) and Massé, G. (U. Plymouth)
Participants: Mylène Bourque (UQAR)Guillaume Massé (U. Plymouth), Simon Belt (U. Plymouth), Michel Poulin (CMN), Lindsay Vare (Plymouth)

Objective 1: An investigation into the use of compound specific biomarkers from sea ice diatoms to determine the presence of past Arctic sea ice – high resolution studies using box core sediments.

Background
Previously, the Plymouth team (GM, SB and LV) have demonstrated that an unusual chemical biomarker, derived from sea ice diatoms, can be detected in sediments below sea ice, thus providing a proxy measure for sea ice cover in the past. Analysis of sediment material collected with the help of Dr. A Rochon (UQAR) and his colleagues during the 2005 ArcticNet cruise revealed the presence of this biomarker across the entire Canadian Arctic Archipelago from the NOW region through to the Beaufort Sea. Notably, analysis of extracted sediments showed significant temporal and spatial variations in the concentration of the sea ice biomarker, indicating variations in sea ice cover in the past and between different locations. The aim of the current fieldwork was to obtain a series of box core sediments across the CAA in order that similar measurements of biomarker concentration could be made during the more recent periods of deposition (10s to 100s of years). These data would then be calibrated against known satellite records of sea ice over the last 30 years, before applying a suitable calibration model to more extended historical datasets obtained previously.
A further aim of the current fieldwork was to collect sufficient amounts of representative species of the Arctic ecosystem in order to be able to perform analyses of their lipid contents and study the transfer of sea ice biomarkers across food chains. Benthic specimens were to be collected using a purpose built Agassiz trawl which was tested for the first time on board.

Sampling
Box core sediments were collected from a range of locations including the NOW region, the eastern edge of Viscount Melville Sound, McClintock Strait, Dease Strait and the Beaufort Sea. Cores

suitable for sectioning were obtained from 12 sites, with surface sediment obtained from a further location in the McClintock Strait (see listing below). Following retrieval, each core was mounted using newly designed and constructed sectioning equipment brought by the team from Plymouth. In general, cores were sectioned according to the following:

0 (surface) – 2.0 cm	1 mm/slice
2.0 – 5.0 cm	2 mm/slice
5.0 – core bottom (15-25 cm)	10 mm/slice

For high resolution sampling, all sections were collected as single samples, bagged and taken by GM and SB to the UK for analysis. Low resolution samples (> 5.0 cm) were divided into 2 portions (A and B); Samples 'A' were taken by GM and SB to Plymouth, samples 'B' were left on-board the Amundsen. In addition to the box cores obtained during Leg 3, the team sectioned 3 box cores obtained during Leg 1. These were at Stations 701, 617 and 707 though only the Station 701 core was sectioned at high resolution (2 mm/slice).

Agassiz: This trawl was deployed for the first time at station 115 and during this deployment; it was felt that additional weight would improve the efficiency of the equipment. It was decided that no weight should be added to the equipment as this first attempt resulted in a net which was full of mud. The correct procedure for deploying the trawl therefore consists in deploying a length of cable corresponding to the depth of the investigated area plus around 40m of extra cable so that the instrument remains at the sea bed during the operations. The trawling operations were usually performed during 5 to 15 minutes (site dependant) at around 1-1.5 knot.
The specimens collected were frozen and taken to the UK by GM and SB for analysis. Briefly, those will be freeze dried and the samples obtained will be extracted and analysed using a combination of open column chromatography and gas chromatography techniques (GC-MS).

Summary of box core locations

LEG 3

Station 115

Sectioning: 0-5.2 cm @ 0.2 cm/slice
5.2-15.2 cm @ 1.0 cm/slice

Summary of species collected for lipid analyses

Ophiura sarsi, Ophiura robusta, Ampharete acutiformis, Ctenodiscus crispatus, Nymphon sp., Und. Amphipods, Mya sp., Sclerocrangon sp., Asterias rubens, Sclerocrangon boreas, Yoldia sp., Gorgonocephalus arcticus, Und. Isopods., Und. Mytilidae.

Further identification work will be carried out at the Université du Québec à Rimouski.

Summary of Agassiz trawl locations

See table below

Objective 2: Biodiversity and secondary productivity of benthic communities in areas of enhanced and reduced ("hot spots" and "cold spots") productivity and diversity in the Canadian Arctic.

Background

It is widely recognized that wide areas of the Arctic are changing from arctic to subarctic conditions. Rapid warming is causing higher water temperatures and reduced ice cover, two factors that will certainly provoke severe ecosystem changes propagating through all trophic levels. Over the past decade, a geographical displacement of marine mammal population distribution has been observed, that coincides with a reduction of benthic prey populations. According to a widely accepted conceptional model, the relative importance of sea-ice, pelagic and benthic biota in the overall carbon and energy flux will shift from a sea-ice algae-benthos to a phytoplankton-zooplankton dominance. In the context of the potential benthic community changes, it is essential to establish benchmarks in biodiversity at key locations in the Canadian Arctic prior to (a) the expected changes in ice cover, ocean chemistry and climate and (b) the future human activities (transport, trawling or dredging, drilling, etc) that are likely to happen in response to the predicted environmental changes. Unlike Canada's two other oceans, we have the opportunity to document pristine conditions before ocean change and exploitation occur. **Our objective** was to describe and compare the biodiversity and secondary productivity of benthic communities in areas of enhanced and reduced ("hot spots" and "cold spots") productivity and diversity in the Canadian Arctic.

Sampling

For the determination of macrofauna structure and composition, sediments were collected with box cores. At each station, a sediment sub-sample of 0.125 m^2, varying to 10-15 cm depth, was passed through a 500 mesh sieve and preserved in a 10 % buffered seawater formalin solution for further identification in the laboratory. The specimens collected in the Agassiz were identified to the lowest taxonomic level and counted. Some species were frozen for further identification.

Preliminary results

Catches in the Agassiz consisted mainly of brittle stars, worms, fishes, molluscs and amphipods. In Viscount Melville Sound, an unexpected sea spider (Fig. 1) was collected, which is only distributed in the Arctic. We also collected an octopus (Fig. 3), some big shrimps (Fig. 2) and sea stars.

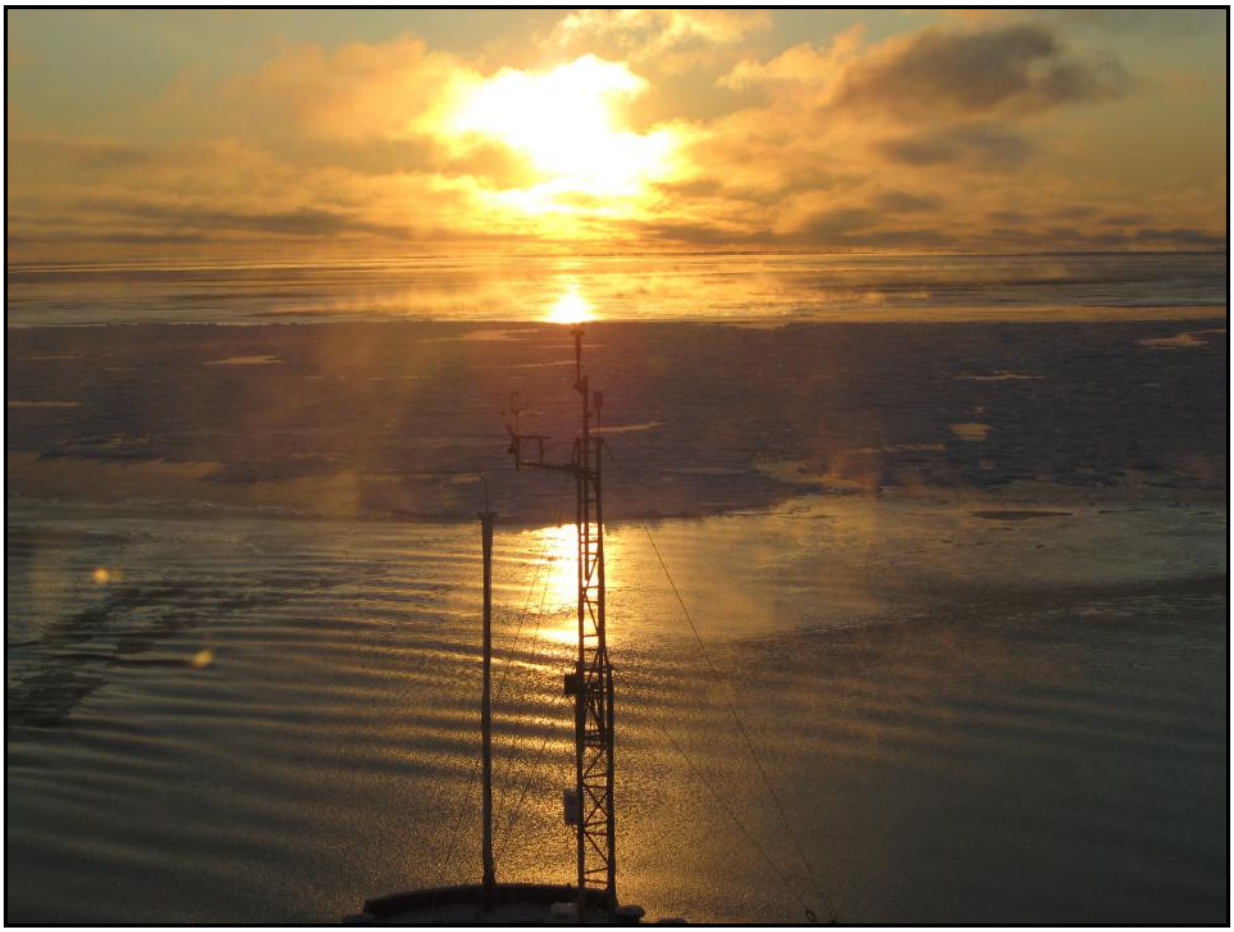
2.6. Team 6

2.6.1. Surface Meteorology and Flux Program

PI: Tim Papakyriakou (University of Manitoba)
Participants: Bruce Johnson, Kyle Swystun

Introduction
The instruments deployed on the CCGS Amundsen as part of the surface meteorology and flux program of the Circumpolar Flaw Lead System Study (CFL, Team 6) provide information on:

(i) bulk meteorology and microclimatology
(ii) detailed information on the air-sea exchange of momentum, heat, radiation and CO_2
(iii) pertinent near surface and surface sea water (sea ice) properties.

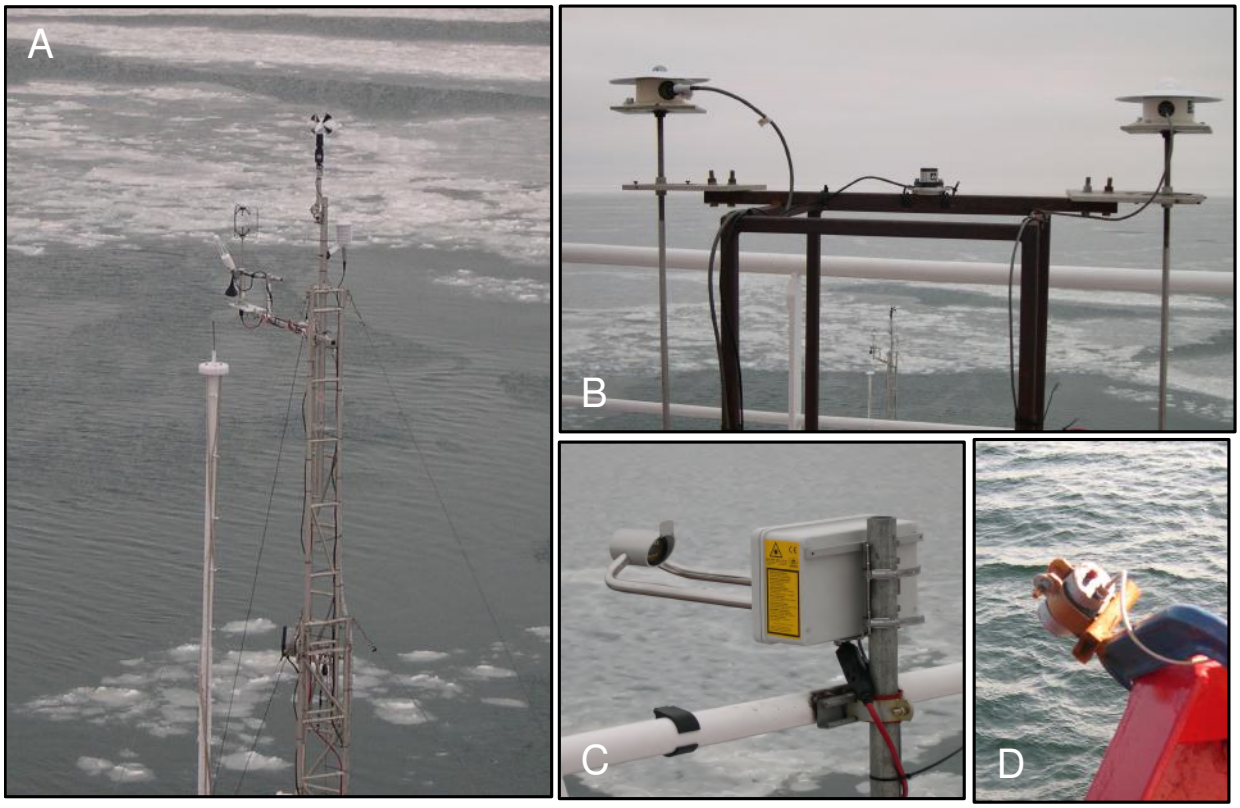


The surface fluxes constitute the upper and lower boundary forcing for the ocean and atmosphere, respectively, and therefore provide a spatial and temporal measure of air-sea coupling across the study sampling region. The objective of the measurement program is to quantify the spatial and temporal rates (and associated variability) in the exchange of energy, momentum and mass (H_2O and CO_2). The objective of the research program, through collaboration with other project researchers, is to better understand the atmosphere's contribution in determining ocean properties (physical, biological, and chemical) through its effect on those oceanic biophysical and biogeochemical processes that are affected by near surface flows of heat, radiation, momentum and CO_2.

Eddy Correlation Flux System

A tower-based eddy correlation flux and surface meteorology system was installed on the foredeck of the CCGS Amundsen during ArcticNet Leg 1 in July 2007. The tower was damaged during Leg 2, so the system was re-installed during the first half of Leg 3 with some modifications (Figure 1a). The base of the tower was strengthened using 4 foot long steel rods that were inserted approximately 2 feet inside the aluminum legs of the tower. Meteorological sensors installed on the 8 m tower measured bulk air temperature, relative humidity, wind speed, wind direction and atmospheric pressure.

Figure 1: Eddy correlation flux and surface meteorology system. a) flux tower on foredeck; b) radiometers on top of wheelhouse; c) laser precipitation monitor on top of wheelhouse; d) infrared temperature transducer on foredeck rail.

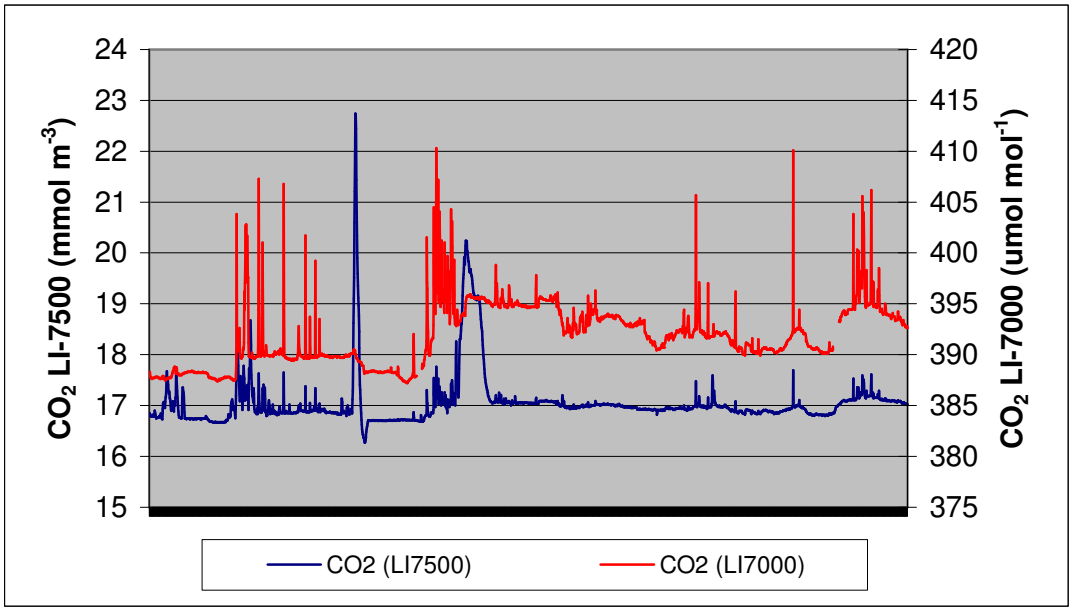


The radiometers for measuring incoming solar (wavelengths 0.3 - 3 μm), long-wave (wavelengths 3 - 50 μm) and photosynthetically active radiation (PAR, wavelengths 0.4 - 0.7 μm) were mounted on a frame installed on the top of the wheelhouse (Figure 1b). An infrared transducer was mounted on the starboard-side of the foredeck to measure surface skin temperature (Figure 1d). A laser precipitation monitor was mounted facing forward on the front rail on top of the wheelhouse (Figure 1c).

The eddy correlation system consists of fast response sensors to measure fluctuations in air temperature, H_2O and CO_2 concentrations, wind speed and ship motion along each of the three principal coordinate axes. Wind speed is measured using a Gill Wind Master Pro sonic anemometer and gas concentrations are measured using two infrared gas analyzers. An open-path IRGA (LI-COR LI-7500) was mounted on the tower at the same height as the sonic anemometer, and a closed-path IRGA (LI-COR LI-7000) was housed in the acquisition container on the foredeck of the ship. A heated and insulated sample tube is used to draw air from the tower to the IRGA inside the container.

Sensor output was collected on Campbell Scientific data loggers. A CR5000 was used for the fast response sensors (sonic anemometer, IRGA's, Motion Pak), with data collected at a frequency of 10Hz and stored on a compact flash card connected to the data logger. Data from the remaining sensors were collected with a CR1000 (foredeck) and a CR23X (wheelhouse) scanned at 2sec intervals and archived as 1 minute averages. Data was retrieved from the data loggers at regular intervals and stored on a computer in the acquisition container.

Figure 2. CO2 molar density (LI7500) and molar fraction (LI7000) for the period 0130h Oct 23, 2007 to 1850h Oct 24, 2007, showing effect of ship's exhaust (all times UTC)

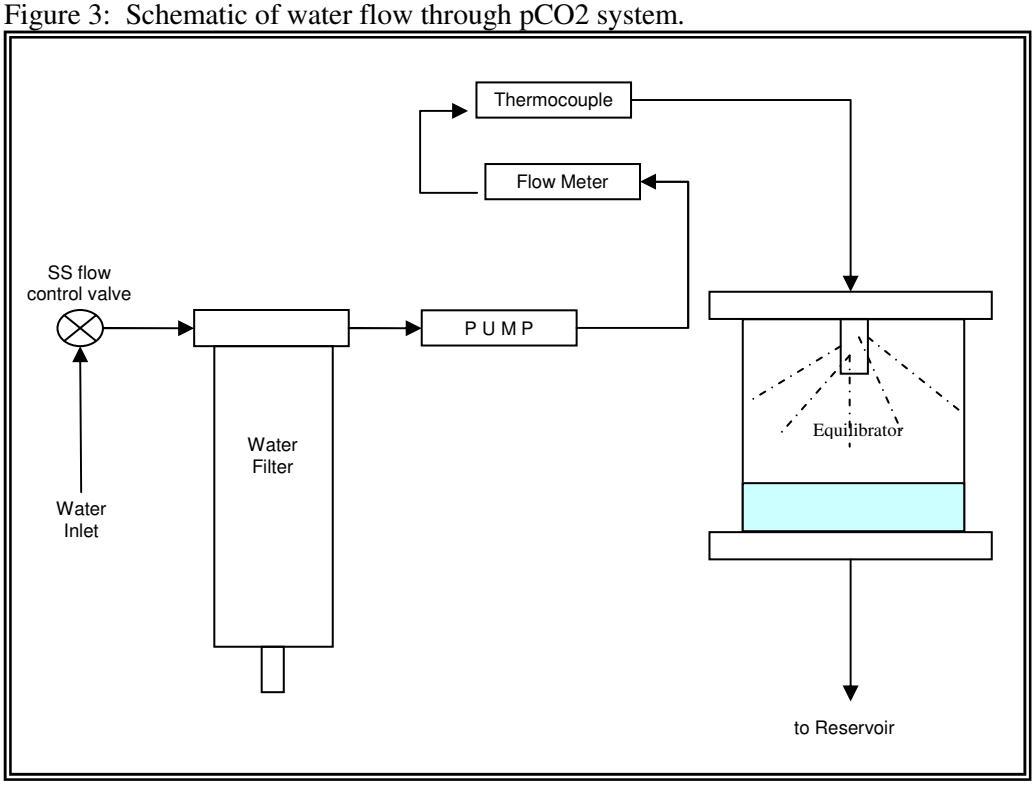


A network of valves, constructed during Leg 1, is used to facilitate the flow of reference gases and calibration gases to the LI-7000 inside the acquisition container. Ultra-high pure N_2 gas is continuously supplied to the reference cell of the gas analyzer at a flow rate of 70-80 mL/min. By manually opening and closing valves, N_2 can be supplied to the reference and sample cells at the same time for zeroing the analyzer, and a calibrated CO_2 gas can be passed through the sample cell for setting the CO_2 span of the analyzer. This system of valves is also used for calibrating the open-path IRGA. To calibrate the LI-7500, the sensor head and electronic control box are removed from the tower and set up in the acquisition container. Calibration of the LI-7000 was done once per day, while calibration of the LI-7500 was done at weekly intervals, or as necessary.

Sea Water pCO_2 Flow-through System

An under-way pCO_2 system, hooked up to the ship's sea water intake, was installed in the forward engine room of the ship during Leg 1 in August 2007. Alterations were made to the set-up, and the system became fully operational on October 23. The principal of the pCO_2 measurement is based on the equilibration of carrier air with sea water and subsequent determination of the CO_2 concentration in the carrier air. In our system, a continuous flow of seawater passes through an equilibration tank (Figure 3). A fixed volume of air is re-circulated continuously through the system to maintain near equilibrium in terms of gas concentration with the flowing seawater. After circulating through the equilibration tank, the air is passed through an infrared gas analyzer (LI-COR LI7000) to measure CO_2 concentration. A network of valves was added to the system to facilitate setting the CO_2 zero and span of the gas analyzer without interrupting the air flow within the equilibration tank. Calibration of the IRGA was done daily in a similar manner to that described for the eddy correlation flux system.

Figure 3: Schematic of water flow through pCO2 system.

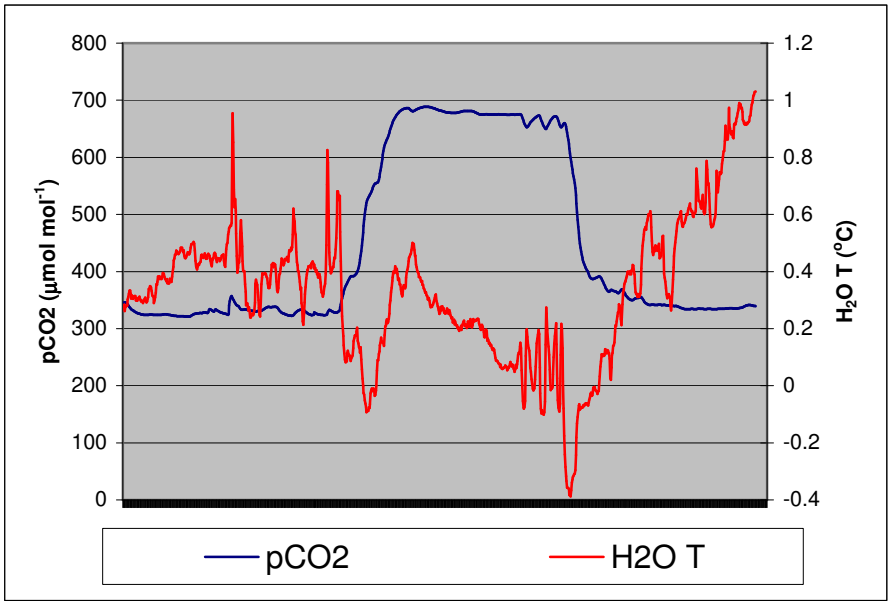


The equilibration tank is constructed with clear acrylic tubing (9"OD, 8½" ID) inset into 1" thick squares of high density polyethylene (HDPE). The internal volume of the tank is 10.5 L (r = 10.8 cm; h = 28.6 cm). Water was drawn from the ship's sea water intake using a centrifugal pump, passed through an 800 micron nylon mesh filter bag, and pumped into the equilibration tank through a "shower head" (Figure 4). The incoming sea water passes through a vortex flow meter and a thermocouple junction before entering the equilibration tank.

Sea water drains from the tank by gravity through an outlet in the bottom HDPE plate into a stainless steel holding reservoir, and then the water is pumped into the ship's waste water outlet. There was ~6 cm (2.2 L) of water maintained in the bottom of the tank, and water flow through the system was maintained at ~2 L/min. Air flow through the remaining headspace (8.3 L) was maintained at 3.5 L/min, providing a residence time of air in the tank of ~2.5 minutes. Output from the gas analyzer, thermocouple and flow meter were recorded by a CR1000 data logger (Campbell Scientific) with a scan interval of 2 sec and archived as 1 minute averages.

Figure 4. Sea water pCO2 flow-through system in the forward engine room.

Figure 5: Sea water pCO_2 and H_2O temperature for the period 2230h Oct 22, 2007 to 1640h Oct 23, 2007 (UTC)



2.6.2. Estimates of arctic air-sea CO2 transfer using QuikSCAT scatterometer

PI: Darek Bogucki & Will Drennan (RSMAS, University of Miami)
Participant: Sarah Woods

Introduction

In order to quantify CO2 exchange on a regional or global scale it is useful to relate the exchange to parameters that are readily measured with remote sensing techniques since satellites can provide global coverage on a daily timescale. Although remote sensing methods allow for better comparison of ocean carbon uptake over changing locations and seasons, there is also variability in oceanic CO2 uptake estimates depending upon how the exchange calculation is formulated, since it is not measured directly by this technique. Many satellite-derived estimates have been obtained using wind speed, but uncertainties of this relationship grow at higher wind speeds. Wave slope, a less commonly measured parameter, may hold a stronger relationship with CO2 exchange than wind speed, providing an opportunity to lower estimate uncertainties.

Current air-sea flux measurements by our group will allow us to determine the air-sea CO2 exchange along the ship track. With a relation between this shipboard exchange measurement and concurrent satellite measurements of wave slope, the satellite wave slope measurements can be used to extrapolate the shipboard CO2 transfer estimates in location and time. As a way of validating this correlation, we are also concurrently measuring wave slope locally by extending a set of laser altimeters (LAWAS) off the side of the ship. The wave slope measurements are timed to coincide with QuikSCAT satellite passes so that we can make a comparison between the wave slopes derived from the satellite signal and the shipboard measured wave slopes, providing a check of the satellite measurement and ensuring that it can be appropriately correlated with the shipboard air-sea CO2 exchange measurement.

During Leg 3, LAWAS was deployed from the foredeck of the CCGS Amundsen to measure wave slope while the QuikSCAT microwave scatterometer passed overhead, taking concurrent surface roughness measurements. The system consists of four RIEGL near infrared (0.9 µm) laser range finders, whose optical heads are mounted 30 cm apart at the corners of a square. Each laser acquires a

time series of the waves directly beneath it. Combining the four data sets, the wave slope will be determined. A motion pack is mounted on top of the deployed optical head to account for movement of the instrument during deployment.

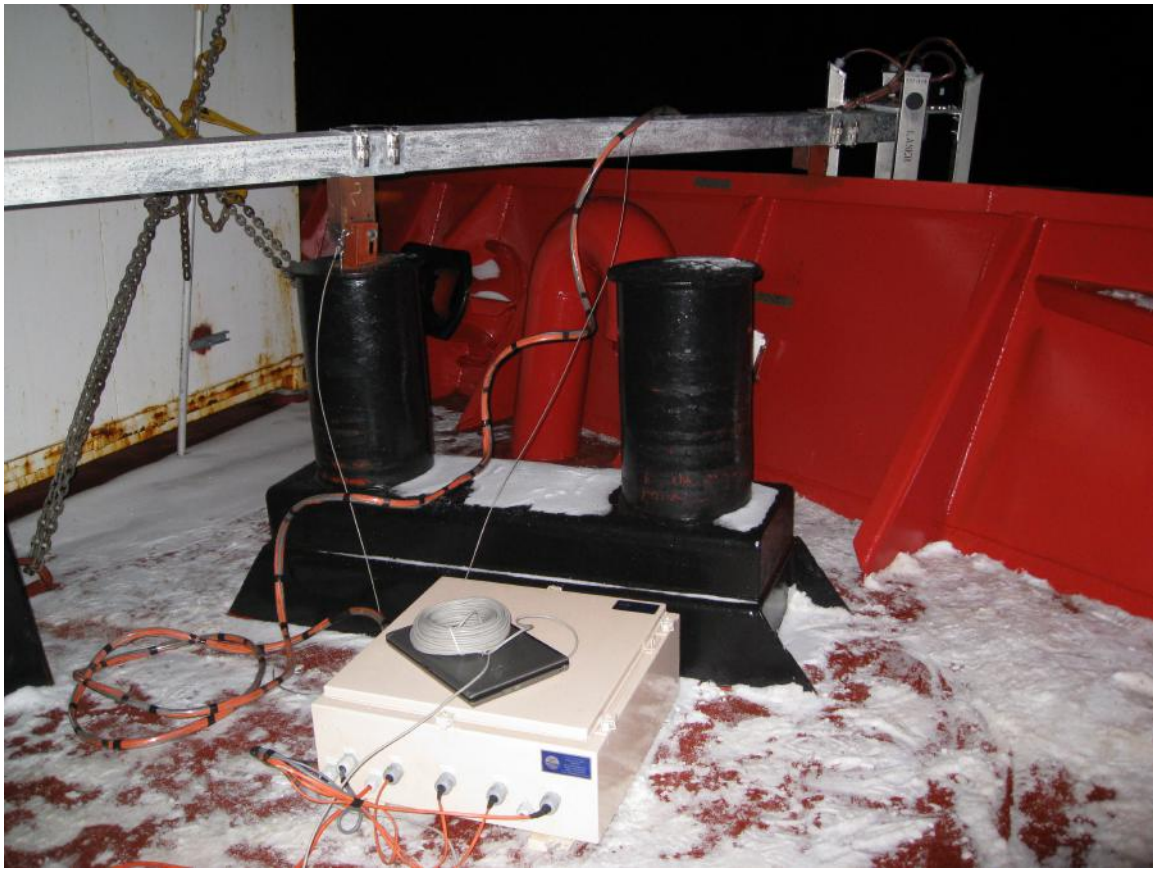


Figure 1: LAWAS deployment setup

Figure 2: LAWAS Optical Head and footprint

Sampling
Each sample consists of four wave height time series given by LAWAS, which will later be converted to a wave slope time series. Each sample is correlated with a QuikSCAT overpass.

2.6.3. Atmospheric Group (SOLAS)

PI: Ann-Lise Norman
Participants: Ann-Lise Norman, Alison Michelle Seguin & Ofelia Rempillo (University of Calgary)

Aerosol measurements:
Atmospheric aerosols were collected on board the CCGS Amundsen using two high volume samplers (hi-vols). The hi-vols were installed above the bridge. One was equipped with SO_2 and particulate filter for the collection of bulk aerosols and their precursors. The other was equipped with a 5-stage cascade impactor for the collection of size-segregated aerosols. Collection of bulk aerosol were done for a period of 24 hours, while collection of size segragated aerosols were done for a period of 3 days. "Field blanks" were also obtained.

DMS measurements:
Atmospheric DMS measurements were also made during the Leg 3 cruise. Samples were collected through a Tenax tube using a portable, battery-operated sampler equipped with flow controller. Samples were collected on the deck containing the hi-vols. For the first half of the leg (Arctic Net) samples were collected every hour for 24 hours. During the second half of the leg (CFL), samples were taken every one to one and a half hour for 6 to 12 hours a day. All samples were analysed on board using a gas chromatograph fitted with a sulphur chemiluminescence detector provided by the Meterological Service of Canada (Sangeeta Sharma).

During the first half (Arctic Net) of the leg. Surface water samples were collected every two hours for DMS analysis. Morning water samples were collected by Sarah-Jeanne Royer (DMS water group) while Night samples were collected by Michelle Seguin and Ofelia Rempillo.

Other Measurements:
CO_2 in the atmosphere was also measured using a LICOR CO_2 analyzer. The difference between CO_2 in the atmosphere and CO_2 in an cylinder of compressed air (yet to be calibrated to international standards) was used to determine the persence of ship stack emissions. Relative humidity and temperature sensors were placed at the level 5 on the exterior of the ship to obtain temperature measurements at two heights so that boundary layer heights could be calculated. Unfortunately, interference from the ship's radio and radar signals rendered the temperature measurements useless.

Preliminary Results:
Chemical and stable isotope analysis of the aerosol samples will be performed after the cruise in laboratories at the University of Calgary.

Logistics:
Jan Bottenheim (Enviornment Canada) expressed an interest this past October in measuring atmospheric DMS between this fall and next when C-SOLAS will use the equipment. Additional cylinders of H_2 and O_2 aboard the ship would facilitate use of the GC-SCD and DMS samplers by Jan Bottenheim's group during the spring. However, due to weight restrictions, spare cylinders were not placed on board. This is unfortunate, as data from the spring would be very interesting to have in addition to the two fall periods, particularly if another group will measure DMS in the water at that time.

Recommendations:

1. The fume hood in the Paleolab needs to be fixed. Putting the ozone exhaust outside causes ice to form in the tubing that blocks the exhaust.
2. Incineration time should be logged
3. A shielded cable and thermometer assembly should be installed in place of the current thermometer outside of deck 5.

2.6.4. Aerosol and Trace Gases (SOLAS)

PI: Richard Leaitch (University of Toronto)
Participants: Steve Sjostedt and Rachel Chang (University of Toronto)

Study Goal:
The primary goal of this study was to follow the sulfur cycle in the atmosphere in collaboration with the other SOLAS groups on board who looked at ocean-atmosphere sulfur exchange. Gas-phase dimethyl sulfide, measured on board with the proton transfer mass spectrometer (PTR-MS), can be oxidized to form sulfur dioxide, also measured on board, which can be further oxidized to sulfuric acid and either nucleate to form new particles or condense onto existing particles. This was monitored using various aerosol size distribution instruments as well as a time-of-flight aerosol mass spectrometer (ToF-AMS). Secondary goals were to measure other trace gases and characterize the aerosol population in a polar marine environment.

Measurement Location:
All of the instruments except for the MOUDI were located in a temperature controlled structure located behind the bridge of the CCGS Amundsen. Approximately 30 ft of ⅜ in stainless steel line was run out to the mast ~10 ft above the bridge for aerosol sampling. A ¼ in teflon line was run parallel to the aerosol sampling line to measure the trace gases. A second shorter line ~ 10 ft was situated above the structure housing the instruments. The PTR-MS measurements were split between the two sampling locations.

Trace Gas Measurements:
An Ionicon PTR-MS was employed to measure multiple volatile organic carbon and sulfur compounds. Some of the species measured were acetaldehyde, acetone, acetic acid, benzene, dimethyl sulfide, hydrogen sulfide, methanol, methacrolein, methyl ethyl ketone, methyl vinyl ketone and toluene. Measurements were obtained continuously on 30 second intervals. Ozone (Thermo Environmental U.V. Photometric Analyzer Model 49) and sulfur dioxide (Thermo Environmental Pulsed Fluorescence Analyzer Model 43 S) were also measured continuously from the mast sampling site.

Aerosol Measurements:
Size distributions of aerosols between 10 – 500 nm were obtained with a sizing mobility particle sizer, total fine particles (> 3 nm) were measured with a condensation particle counter and size distributions for the coarse fraction (0.5 – 20 μm) were measured with an aerodynamic particle sizer. Real-time continuous measurements of aerosol composition were obtained with a ToF-AMS for the first 3 weeks of the measurement campaign. Aerosol composition was also obtained from a MOUDI impactor placed above the bridge.

Preliminary Results:
The data needs to be quality checked due to frequent fumigation of the inlet lines of smoke stack emissions.

Recommendations:
1. An incineration log would be helpful
2. Samples of the fuel and engine lubricants used on board would also be good

2.6.5. DMS(P) Cycling (SOLAS)

PIs: Maurice Levasseur et Michael Scarratt
Participants: Sonia Michaud (IML-DFO), Sarah-Jeanne Royer (Université Laval), Myriam Luce (Université Laval), Michael Scarratt (IML-DFO)

Nous avons mené deux projets à bord de l'Amundsen. Le premier est la collecte de donnée pour la maîtrise de Myriam Luce. Ce projet vise une meilleure compréhension de la distribution du diméthylsulfure (DMS), un gaz produit par le phytoplancton et bactérioplancton marin à partir du diméthylsulfoniopropionate (DMSP). Une fois oxydé dans l'atmosphère, ce gaz sert de noyau de condensation des nuages et ainsi diminue la quantité de lumière qui atteint le sol. Nous tentions de

déterminer quels facteurs déterminent la production de DMS dans l'océan Arctique. Pour ce faire, notre équipe a effectué plusieurs mesures et expériences à bord de l'Amundsen.

D'abord, nous avons mesuré la concentration du DMS et de DMSP à plusieurs profondeurs de la colonne d'eau : 100% de lumière incidente, 50%, 5%, 0.2% et au maximum de chlorophylle profond. En surface, nous avons prélevé de l'eau pour préserver du phytoplancton et du bactérioplancton afin de déterminer leur taxonomie et abondance. Le phytoplancton sera identifié par observation au microscope de retour au laboratoire. Les communautés bactériennes seront caractérisées au moyen de la technique CARD-FISH, qui est une hybridation des cellules avec des sondes fluorescentes spécifiques à divers clades bactériens. Nous avons également fait des incubations d'eau de mer avec des ajouts en concentrations traces de DMSP marqué radioactivement au ^{35}S. Ces incubations de trois heures nous permettent de mesurer la consommation de DMSP et déterminer la vitesse de transfert du soufre vers divers réservoirs. Nous avons mesuré la production de DMSP particulaire, l'incorporation dans les macromolécules, la production de DMS et la production de composés soufrés dissous. Finalement, nous avons effectué des incubations de 22 heures en présence de DMSP marqué pour la technique MAR-CARD-FISH. Cette technique nous permet de déterminer quelle proportion de chaque clade bactérien consomme le DMSP.

Nous avons également échantillonné le DMS en continu du 8 au 14 octobre. Nous mesurions le DMS dans les eaux de surface à toutes les deux heures en prélevant de l'eau à la pompe de la salle des machines. L'objectif était de permettre à l'équipe d'Ann-Lise Norman, étudiant le DMS dans l'atmosphère, d'avoir des données de DMS dans l'eau concordant avec son échantillonnage. Ce monitorage en continu nous a permis de constater la présence d'un fort cycle jour-nuit dans les concentrations de DMS. Trouvant le phénomène intéressant, nous avons décidé de suivre la concentration de DMS dans l'eau à une station fixe pendant 24 heures. Nous l'avons fait les 23 et 24 octobre à la station 407. Nous avons fait quatre profils verticaux de DMS et DMSP répartis sur 24 heures. Nous avons préservé des bactéries pour la technique CARD-FISH sur les mêmes rosettes. Deux fois, soit une fois le jour et une fois la nuit, nous avons préservé du phytoplancton et avons incubé de l'eau de mer avec du ^{35}S. Nous avons aussi prélevé de l'eau de surface à l'aide d'un seau aux deux heures pour connaître la concentration de DMS et DMSP.

Distribution de l'oxyde nitreux (N_2O) dans l'arctique (Scarratt)

Le second projet est mené par Michael Scarratt et concerne l'étude de l'oxyde nitreux, aussi nomme le protoxyde d'azote, ou N_2O. Ce gaz biogène est produit par l'activité bactérienne comme sous-produit du cycle d'azote lors de la nitrification et la denitrification. Dans l'atmosphère, le N_2O est un puissant gaz à l'effet de serre, troisième en importance après le gaz carbonique et le méthane. Il est présent aux concentrations moyennes d'environ 300 ppm dans l'air, et environ 8 nM dans les eaux de surface, mais la concentration dans l'eau est très variable selon les conditions océanographiques et biologiques. L'objectif principal de l'étude en 2007 est de déterminer la distribution du N_2O dans les eaux de surface sur une radiale est-ouest traversant l'archipel arctique canadien. Des échantillons ont été récoltées aux mêmes stations et aux mêmes profondeurs que pour le DMS, incluant quelques stations ou des profils complètes jusqu'au fond ont été réalisé. Un total d'environ 275 échantillons seront ramenées à l'IML pour l'analyse, car le système GC à bord est configure pour détecter uniquement les molécules contenant le soufre. Pour détecter le N_2O et d'autres composées de l'azote, une modification du détecteur est requise. Notre système GC à l'IML sera modifié ainsi, et les données seront disponibles pendant l'hiver. Une coordination a été faite avec Roxanne Maranger du programme CFL qui échantillonne aussi le N_2O, et à deux stations (1606 et 1902) nous avons échantillonné ensemble aux mêmes profondeurs afin de permettre une inter-calibration de nos deux systèmes.

Échantillonnage effectué:
Nous avons effectué le travail suivant aux stations suivantes

2.7.1. Barium

PI: Helmuth Thomas
Participant: Friederike Prowe (Dalhousie University)

In the Canadian Arctic, barium (Ba) is mainly released from the North American continent and can therefore be used as a tracer for terrestrial freshwater input. Together with ^{18}O, a tracer for freshwater input from precipitation and ice melt, all freshwater sources to the Arctic can be quantified.

Throughout Leg 3, samples for barium were taken from the rosette parallel to samples for ^{18}O, at approximate depths 5, 10, 25, 50, 75, 100, 150, 200 and 500 m. 15 ml nalgene bottles were rinsed three times, then filled and spiked with 15 µl concentrated HCl. Sample bottles were sealed with parafilm and taken for later analysis using isotope dilution mass spectrometry.

2.7.2. Carbon system (CFL Teams 6 & 7)

PIs: Helmuth Thomas & Al Mucci
Participants: Constance Guignard (McGill University) and Friederike Prowe (Dalhousie University)

The ocean's exchange of carbon dioxide with the atmosphere is governed by the biogeochemical cycling of carbon and physical processes throughout the water column, which determine the concentration of dissolved inorganic carbon in the surface waters. Of the seven relevant carbon system parameters, a minimum of two are needed to calculate the others and fully describe inorganic carbon chemistry, overdetermination of the system being beneficial. During ArcticNet/CFL leg 3, a total of 445 samples were analyzed for dissolved inorganic carbon (DIC) and total alkalinity (TA), pH was determined for 248 samples, yielding two/three relevant parameters.

During the first half of leg 3 (Sep 27 to Oct 18), 500 ml water samples were collected from the rosette at several depths for determination of DIC and TA. Samples were usually first to be taken from the niskin bottles, or preceded only by dissolved oxygen at individual casts and depths. Due to the presence of a group analysing for mercury, with the exception of three stations samples were not spiked with $HgCl_2$, but stored in the dark at 4 deg C and analyzed within 24 hours of sampling.

DIC and TA were analyzed on board using a VINDTA 3C (Versatile Instrument for the Determination of Titration Alkalinity) by marianda. TA was determined by titrating a volumetrically accurate subsample using HCl as titrant, and a set of three electrodes, a Ross pH electrode,a reference AgCl electrode and an auxillary platinum electrode. For measuring DIC, a volumetrically determined subsample was acidified with 8.5% H_3PO_4 to convert all inorganic carbon into gaseous CO_2. The CO_2 was stripped out of the sample using ultra-pure N_2 gas, transferred into a coulometric titration cell and detected using the coulometric method (Johnson et al., 1993).

During the second half of leg 3 (Oct 18 to Nov 08), 500 ml water samples were collected as before, but spiked with 200 µl of saturated $HgCl_2$ solution and analyzed on board before the end of the leg. DIC was determined as before using the VINDTA. Afterwards, TA was determined using a TIM 865 automatic titrator from Radiometer Analytical. All TA samples were analyzed in duplicates.

In addition to DIC and TA, water samples for pH were taken from the same bottles directly after DIC/TA samples. pH samples were collected in plastic bottles and analyzed immediately using a HP 8453 spectrophotometer. pH will be calculated using the absorbances measurements obtained from the coloration of water samples with Phenol Red and Cresol Purple.

2.7.3. Carbon & nutrients fluxes

PI: Jean-Éric Tremblay
Participants: Jean-Éric Tremblay, Jonathan Gagnon & Johannie Martin (all at Department of Biology, Laval University)

Rationale

The Arctic climate displays high inter-annual variability and decadal oscillations that modulate growth conditions for marine primary producers. Much deeper perturbations recently became evident in conjunction with globally rising CO_2 levels and temperatures (ACIA 2004; Comiso 2003). The thickness and extent of Arctic sea-ice decrease rapidly (Johannessen et al. 1999; Rothrock et al. 1999) and the ice-free season is extending both in the Arctic (Laxon et al. 2003) and subarctic (Stabeno & Overland 2001). Models predict further reductions in ice cover (ACIA 2004). These changes entail a greater penetration of light into surface waters, which is expected to bolster phytoplankton production (Rysgaard et al. 1999), food web productivity and CO_2 drawdown by the ocean. At present, phytoplankton production varies by two orders of magnitude across the Canadian Arctic, but the forcing mechanisms are poorly understood and quantified. In the Canadian Archipelago, the productivity of phytoplankton is likely to be limited by light or the supply of allochtonous nitrogen, depending on ice conditions. The supply of allochtonous nitrogen is influenced by climate-driven processes, mainly the large-scale circulation, river discharge, upwelling and regional mixing processes. Over most of the western Arctic, and especially the Beaufort Sea, the concentrations of inorganic nitrogen (i.e. nitrate, nitrite and ammonia) at surface remain low throughout the year and the phytoplankton possibly depend on local recycling and the dissolved organic nitrogen (DON; e.g. urea, amino acids and primary amines) supplied by rivers. A large portion of the phytoplankton biomass is typically located within subsurface chlorophyll maxima (SCM). SCM productivity is possibly in balance with the episodic supply of nitrate across the halocline and/or the supply of ammonium and nitrate by local recycling and nitrification, respectively. Despite the importance of SCM for the food web and CO_2 fluxes, little is known about their structure, turnover and susceptibility to environmental variability and change.

Objectives

The main goals of our team for leg 3 of ArcticNet 2007&CFL were to **(1)** establish the horizontal and vertical distributions of phytoplankton nutrients and the influence of different processes (e.g. mixing, upwelling and biological processes) on these distributions, **(2)** characterize the detailed vertical structure of chlorophyll-*a* with respect to irradiance, nutrient supply and physical structure, **(3)** experimentally assess causal relationships between phytoplankton productivity and the availability of light **(4)** determine the utilisation of different sources of inorganic and organic nitrogen by phytoplankton, and **(5)** experimentally assess the relationships between nitrogen concentration, temperature, photosynthesis and the kinetics of nitrogen uptake. Ancillary objectives were to calibrate the *SeaPoint* fluorometer and *ISUS* nitrate probe attached to the Rosette.

Methods

Samples for inorganic nutrients (ammonium, nitrite, nitrate, orthophosphate and orthosilicic acid) were taken at all rosette stations (see Table 1) to establish detailed vertical profiles (see Fig. 1 for vertical sampling resolution). Additional samples for dissolved organic nitrogen (DON) and urea were taken at stations where incubations were performed. Ammonium was determined immediately after collection using modifications of the manual fluorometric method (e.g. Holmes et al. 1999). Urea samples were stored frozen and DON samples were preserved with acid and stored in the dark at 4°C for post-cruise determination. The concentrations of nitrate, nitrite, orthophosphate and orthosilicic acid were determined on fresh samples using an Autoanalyzer 3 (Bran+Luebbe) with colorimetric methods adapted from Grasshof (1999).

Samples for the natural abundance of ^{15}N and ^{13}C in particulate organic matter were taken at 5 m and in the chlorophyll maximum at stations where incubations were performed (Table 1). Volumes ranging from 12 to 20 liters were filtered onto 47 mm pre-combusted GF/F filters with a peristaltic pump and the filters were desiccated at 60°C in a drying oven. These data will be used for nitrogen uptake calculations and to assess the nitrogen status of phytoplankton communities.

SetCol protocol (Bienfang 1981) was carried with water from the chlorophyll maximum at the stations where incubations were performed to measure the sinking rate of the micro algae cells. Fractions from the top, the middle and the bottom part of the column were filtered on GF/F filter and extracted with acetone to determine the chlorophyll concentrations. Samples for the taxa composition were taken in the top, the middle and the bottom fraction in a second column and were stored with acid lugol for a post-cruise analysis.

The relationship between light and the uptake of C and N by phytoplankton (light-gradient incubation in Table 1) from the chlorophyll maximum was assessed using dual labelling with stable isotopes of C and N in four light-gradient modules (10 light intensities). Temperature was maintained at *in situ* levels with a chilling circulator. Samples from all modules were spiked with ^{13}C-bicarbonate; two modules received saturating additions of ^{15}N-nitrate, ^{15}N-ammonium (or ^{15}N-urea, or ^{15}N-nitrite), and the other two trace additions. Incubations were terminated by filtration onto 24-mm GF/F filters. All filters were desiccated at 60°C and stored dry for post-cruise determination of isotopic enrichment and particulate organic carbon and nitrogen.

The effect of temperature on photosynthesis and the kinetics of nitrate, ammonium or nitrite uptake were determined in two laboratory incubators maintained at 0 and 6°C with high-capacity chilling circulators. Illumination was provided by sun-simulating fluorescent tubes. For each incubator, bottles were spiked at 6 different concentrations with the target ^{15}N-labelled nitrogen source. The nitrate bottles were also spiked with ^{13}C-bicarbonate.

The effects of incubation treatments (variable nutrient additions, temperature and light conditions) on the photosynthetic characteristics of phytoplankton were assessed by Pulse Amplitude Modulated fluorometry (PAM; Heinz-Walz). Nitrate data were used to calibrate the ISUS nitrate probe. Calibration of the Rosette fluorometer was achieved by comparing the instrument's output with

extracted chlorophyll *a* and PAM data. The Phytoflash system was powered by a CTD (SBE-19) and deployed in self-contained mode from the front deck (nighttime).

Preliminary Results

Figure 1 shows chlorophyll fluorescence and the concentrations of nitrate, nitrite, silicate and phosphate along the section of the North Water Polynya in the Baffin Bay. Nutrient concentrations were typically low in the upper mixed layer, reflecting prior utilization by diatoms. The nutrient deficit extended deeper in the west, just east of the sill, presumably reflecting biological consumption upstream in the southbound Arctic outflow. This scenario is consistent with the relatively deep extent of chlorophyll fluorescence in the region. Isopleths were widely spaced on the vertical, which is indicative of relatively weak density stratification at the onset of wind-driven mixing in autumn. By contrast, isopleths were closely spaced in the east, where the vertical stratification remained strong due to reduced wind exposure.

The chlorophyll maxima on the section seem sited on the nitracline in the western part of the bay. This result tends to prove that the growth of the phytoplankton is limited by the contribution in new nitrogen form (nitrate). This kind of relationship suggests that the phytoplankton lowers progressively the nitracline during the ice-free season until it reaches the depth (ca. 70 metres) where the light is inefficient to support a gross growth which seems happen in the eastern part of the bay.

2.7.4. Phytoplankton & primary production

PIs: Michel Gosselin, Michel Poulin.
Participants: Michel Poulin (CMN) and Lindsay Vare (Plymouth), with part-time assistance from Geneviève Tremblay (ISMER)

This ArcticNet component of this project (Leg 3A) focused on understanding the development of the summer-fall phytoplanktonic communities along an east to west environmental gradient in the Canadian High Arctic, whereas the CFL component (Leg 3B) looked specifically at how the atmospheric, oceanic and hydrologic forcing of sea ice will dictate the overall seasonal production of phytoplankton in the flaw lead and adjacent fast ice.

The main objective is to determine the environmental variables that govern the abundance, composition and production of the summer-fall phytoplanktonic communities in the Canadian High Arctic from the North Water in Baffin Bay to the Mackenzie shelf in the Beaufort Sea, including the North-West passage. This second ArcticNet cruise (Leg 3) brought us to Baffin Bay, the Northwest Passage and the Beaufort Sea, including a suite of stations as part of the Circumpolar Flaw Lead

(CFL) system study in the Beaufort Sea southwest of Banks Island. The main goal of ArcticNet was to compare the phytoplanktonic communities between the eastern and the western Arctic in terms of algal species composition and abundance and to establish the relationships between the environmental variables and the changes occurring in the abundance, the species composition and the primary production of the arctic planktonic microflora. The following hypotheses will be tested (1) a nutrients gradient from the eastern to the western Arctic will influence the species composition of the phytoplankton, (2) a temperature and salinity gradient from the eastern to the western Arctic will affect the species composition of the phytoplankton, and (3) the summer-fall phytoplanktonic communities of the eastern Arctic are more productive than the ones of the western Arctic. The CFL project will focus on the western Arctic region, south-west of Banks Island, tempting to solve the following questions: 1) How do the landfast and flaw lead regions differ in the timing and rates of primary production? 2) Is the phytoplankton community composition and structure different between these two regions? and 3) Is biological production in these regions light and/or nutrient limited?

Water sampling was conducted with a CTD-rosette system collecting water at optical depths corresponding to 100%, 50%, 30%, 15%, 5%, 1% and 0.2% surface irradiance, at the deep maximum chlorophyll (Chl max), and at 75 m and 100 m. Six stations were visited in the Baffin Bay region (101, 105, 108, 111, 115, 134), six stations in the Northwest Passage (301, 302, 308, 309, 310, 314), and 20 stations in the Amundsen Gulf – Beaufort Sea region (405, 407, 408, 420, 434, 435, 437, 1000, 1100, 1110, 1116, 1200, 1216, 1600, 1606, 1800, 1806, 1902, 1908, 1916). Total and fractionated chlorophyll (Chl) and chlorophyll > 20 µm were measured at each corresponding optical depth, the Chl max, at 75 m and 100 m at each sampling site whenever feasible. Routine analyses performed on seawater are indicated in Table 1. Particulate organic carbon (POC) and nitrogen (PON) were done at 50% and 15% surface irradiance, the Chl max and at 100 m. Pico/nanoplankton and bacteria (Pico/Bact) were done at 50%, 30%, 5% and 1% surface irradiance, and at Chl max and 100 m. Planktonic cells were collected at 50% and 15% surface irradiance and at Chl max for species composition and abundance. Dissolved (DOC) and total organic carbon (TOC) were done at 50% and 15% surface irradiance, and at Chl max and 100 m. Samples for pigment analysis by high pressure liquid chromatography (HPLC) were collected at the Chl max only for ArcticNet stations plus at 50% surface irradiance for CFL stations. Protists < 20 µm and > 20 µm for epifluorescence microscopy and FISH were collected at 50% surface irradiance and at Chl max for CFL stations only. Stations 301, 420, 1100 and 1800 were sampled at night time with no Secchi deployment, therefore, fixed water depths were used, while stations 1908 and 1916 were sampled from the moon pool at fixed water depths.

Primary production experiments were conducted at only five sampling sites in the Canadian High Arctic during September-November 2007 (101, 108, 115, 302, 309), due to bad sea conditions which contributed to the destruction of the front deck incubator; primary production experiments were stopped after station 309. Water samples were collected at seven optical depths (100%, 50%, 30%, 15%, 5%, 1% and 0.2% surface irradiance), inoculated with ^{14}C and incubated on the front deck of the ship for 24 h. Water samples at Chl max were incubated to the nearest optical depth. After the incubation, filtrations were performed in the Radvan and scintillation vials were counted aboard the ship in the scintillation counter.

We also recorded continuously the incident light with a PAR sensor (Li-Cor) located on a flat surface on top of a container in front of the ship. At almost all stations sampled, we performed underwater light profiles with a PNF.

Acknowledgements
This project was supported by a Network of Centers of Excellence Grant (ArcticNet), Discovery grants from the Natural Sciences and Engineering Research Council (NSERC) of Canada, IPY-CFL to Michel Gosselin and Michel Poulin, and by a research grant from the Canadian Museum of Nature to Michel Poulin. We are grateful to the Canadian Coast Guard captain, Lise Marchand, officers and crew of the *CCGS Amundsen* for their skillful support during the joint ArcticNet-CFL 2007 leg 3 campaign. We acknowledge the invaluable support of the chief scientist, Jean-Éric Tremblay, during

the expedition as well as several of the scientific staff who provided some assistance in the conduct of our sampling program, and in particular Geneviève Tremblay.

Recommendations
In order to avoid further destruction of the front deck incubator, a movable steel structure should be built to cover the incubator when bad sea conditions prevail, or think of a better protected location on the ship.

The PAR Li-Cor sensor should perhaps be relocated somewhere else than the top surface of the front deck container on starboard because of night ship illumination for sailing and/or front deck operations.

We should think of a proper way to transport water sample bottles (heavy) from the rosette shack to lower deck laboratories.

2.7.5. Short-term vertical fluxes

PI: Christine Michel (Freshwater Institute Winnipeg, DFO)
Participant: Geneviève Tremblay (ISMER, UQAR)

Introduction
Sediment traps have been used to estimate the sinking flux of organic material in the ocean and to assess the composition of that flux. There are two pathways to describe organic carbon in the water column. 1) Phytoplankton carbon can be transferred to the higher trophic level by zooplankton grazing. Part of this carbon can be used by other organisms including fish, mammals and bird, while another part may be exported at deeper depth in the form of fecal pellets (feces). This pathway favors transfer to the pelagic ecosystem. 2) On the other hand, phytoplankton carbon that is not used can be directly exported through sedimentation of intact cells. This pathway leads to food input to the benthic (sea floor) community.

Objectives
This study investigates the biogeochemical cycling of carbon and other organic constituents through the use of short-term particle interceptor traps. The general objective of this study is to characterize the sinking export of carbon and organic material from the euphotic zone (magnitude and composition of the sinking fluxes and material), and the transformation of material during its sinking to depth. This research aims at understanding how climate-related changes in the distribution, timing, magnitude and type of primary production may affect the fluxes of material to the benthic and pelagic food webs.

Methods
During the ArcticNet (27th of September to 17th of October 2007) and CFL program (18th of October to 8th of November 2007), we deployed the traps at six stations throughout the Canadian High Arctic. Of the 12 full stations (full and mooring stations) originally scheduled, only 6 deployments could be performed. Heavy ice condition at stations 101, 1116, 1216, and 1200 did not permit FST deployment. Because of a tight schedule and strong winds, station 437 was transformed into basic station, giving no time for FST deployment. Station 1806 was too shallow for deployment.

The traps were PVC cylinders with an internal diameter of 10 cm and a height/diameter ratio of 7. Before each deployment, seawater collected at 200m deep at a previous station was filtered through 0.22 µm filter membranes. The traps were filled with the filtered seawater to create a dense layer. A series of five PVC cylinders were installed on a line at each sampling depth (50m, 100m, and 150m) in order to collect enough material to perform subsequent analyses. At the surface, the trap line was attached to a positioning system (ARGOS and radio beacon) and a series of small floats (Viny floats) to minimize vertical motion. The traps were deployed for a period of 12-24 hours. Upon recovery, the traps were placed in a dark cold room for 8 h. After allowing the sediment to settle, the supernatant was removed and the bottom volume (ca. 1000ml) of the traps was kept for analysis. Samples were

analyzed for particulate organic carbon and nitrogen (POC/PON), dissolved organic carbon (DOC) and nitrogen (DON), stable isotopes (Isotopes), biogenic silica (BioSi), total chlorophyll *a* and phaeopigments (total chl*a*), exopolymeric substances (EPS) phytoplankton composition and abundance (Cells), fecal pellet abundance (FP), and DAPI.

Another aspect of this project is to evaluate the spatial and vertical distribution of dissolved organic carbon and nitrogen in Arctic marine waters, as these constituents play important roles in the cycling of organic material on the shelves. Water column samples were taken at all basic and full stations throughout the Canadian High Arctic for a total of 30 stations.

2.7.6. Bacterial processes

PI: Roxane Maranger
Participant: Roxane Maranger

Scientific Objectives CFL: As part of team 7, the goals of my team are to measure bacterial C production, community respiration (directly and via ETS activity) and bacterial biomass, in order to elucidate the role of bacterial in ecosystem C processing. Another objective for CFL will be to measure N2O concentrations in the water column to understand whether this by-product of nitrification and denitrification accumulates a

Objectives Leg 3B: My main goal for this leg was to set up our stations, assure we had all the necessary materials we needed for legs 4-10, do some preliminary tests of new methods and see the sampling site for the first time. I am familiar at working in temperate lakes and need to adjust methods accordingly.

Bacterial production rates are low but measurable.
Respiration using the Fibox and sensor is difficult to detect. We will continue testing, but put more effort in ETS as back-up. Also had difficulties with chamber temperature stability and set up where the Fi-Box incubations were taking place.
I experimented with different types of filtration to try to streamline ETS filtration.

October 18-25: lab and instrument set up and calibration.

2.8. Team 8

General objective
The question this project hopes to answer is how climate variability in physical forcing and the biogeochemical response to this primary forcing will affect organic contaminants and mercury (Hg)/methyl mercury (MeHg) cycling. Ultimately, we propose to relate changes in delivery and biogeochemical cycling of these contaminants to their levels in fish, marine mammals and the people who consume these tissues as part of their traditional diets.

An additional sampling campaign of PFOA (perfluorooctanoic acid) and PFOS (perfluorooctane sulfonic acid) was undertaken during ArcticNet and CFL 2007-2008. The program is designed to obtain a detailed picture of PFOA and PFOS concentrations in near shore and open ocean sites in the Canadian arctic.

2.8.1. Organic contaminants

PI: Gary Stern (DFO, Freshwater Institute)
Participants: Allison MacHutchon & Joanne DeLaronde (DFO, Freshwater Institute)
Monika Pucko (PhD candidate, University of Manitoba)

Hexachlorocyclohexane (HCH)

Technical HCH is a mixture of several isomers, the most abundant being α-HCH (60-70%), γ-HCH (5-12%) and β-HCH (10-15%). Technical HCH and pure γ-HCH (lindane, pesticide active isomer) have been used for over 50 years and are now ubiquitous in water throughout the northern hemisphere with the highest levels found in the surface water layers near pack ice in the Arctic Ocean.

Technical HCH was banned or heavily restricted by China, the former Soviet Union and India between the mid-1980s and 1990. Concentrations of α-HCH in arctic air responded quickly to these large-scale usage changes and declined by an order of magnitude from the early 1980s to mid-1990s in steps that closely matched global usage and emission estimates. As a consequence, the direction of net gas exchange in arctic waters reversed from deposition in the 1980s to air-water equilibrium or volatilization in the mid-1990s.

The α-isomer is the prominent in Arctic air, water, biota and soil, and moves northward via cold-condensation, a process whereby the contaminant evades into the atmosphere, drifts with atmospheric currents, and condenses in colder climates where at colder temperatures increasingly favours the water and extensive ice cover inhibit further evasion. Hence the contaminant accumulates disproportionately in the Arctic.

Water sampling
Water (4L) was collected from the rosette at all full and basic stations. At the surface, a plastic bucket was used to collect the water. Where feasible, transects across water bodies were collected. In the lab, water was pumped through a glass-fiber filter followed by an ENV+ solid-phase extraction (SPE) cartridge using peristaltic pumps. On ArcticNet leg 3/CFL leg 1, we collected 29 profiles, usually consisting of 9 depths, with the emphasis on the upper water column. Filters and cartridges are frozen and brought back the Freshwater Institute for analysis. $^{18}\delta O$ and salinity samples were also collected at each site and depth where HCH samples were taken.

HCH water filtration (Aft chemistry lab)

Air Sampling
The air sampler was set up on the bow of the ship on the starboard side for all full stations, most basic stations, and several transects. Samples are collected on a glass fiber filter and polyurethane foam (PUF) for analysis of organic contaminants. Air samples collection time ranged between 4 and 23 hours. A total of 32 samples were collected. Filters and PUFs were frozen at -20°C and shipped frozen back to the FWI for HCH contaminant analysis.

Air sampler / Ptarmigan perch

Ice sampling
Ice samples for HCHs concentration and enantiomeric composition were collected at each basic and full station where the newly formed ice was present (Table 1). The samples for oxygen isotope composition ($\delta^{18}O$) and salinity were taken along with all ice samples. The ice samples were collected in collaboration with team 2 and the ice microstructure analysis was made on most of them (except from stn. 1000 and stn. 1600) (see team 2 cruise report). In cases where more than one type of ice was present, 2 ice samples were collected. The total of 12 samples of newly formed sea ice for HCHs, $\delta^{18}O$ and microstructure analysis was collected.

Table 1 Ice sampling locations for HCHs during leg 3B

Date	Station	Type of ice	HCH sample #	$\delta^{18}O$ sample #
26 Oct 07	1000	slushy pancake ice	AN07-LV-268	284
27 Oct 07	1110	nilas	AN07-LV-285	301
28 Oct 07	1116	nilas	AN07-LV-294	310
29 Oct 07	1216	nilas	AN07-LV-301	312
31 Oct 07	1200	consolidated pancake ice	AN07-LV-310	321
01 Nov 07	1600	consolidated pancake ice (slushy pieces collected)	AN07-LV-320	331
02 Nov 07	1606	consolidated pancake ice (slushy pieces collected)	AN07-LV-327	338
03 Nov 07	1902	nilas (smooth with nidle-like frost flowers and no slushy layer)	AN07-LV-337	348
03 Nov 07	1902	grey ice with 0.5-1 cm of snow on top	AN07-LV-338	349
05 Nov 07	1908	big pancake floes with a 1 - 1.5 cm layer of snow on top	AN07-LV-347	359
05 Nov 07	1908	nilas from between big	AN07-LV-346	358

		pancakes with nidle-like frost flowers and a thin (a few mm) slushy layer on top		
06 Nov 07	1916	grey ice with a thin slushy layer (a few mm) and a lot of big shining conical-like frost flowers on top	AN07-LV-349	361

Ice samples were collected from the ice cage. When the ice was thin enough, the ice chipper was used. In case of thicker ice (>15 cm) the ice cores were taken. The total of 4-8 L of melted ice was pumped through a glass-fiber filter followed by an ENV+ solid-phase extraction (SPE) cartridge using peristaltic pumps. The cartridges and GFFs were stored in -80 °C and brought to the DFO (Winnipeg) for further chemical analysis.

Ice cage/ice corer (Pascale Collin and Phil Hwang)

Perfluorooctanoic acid (PFOA) and perfluorooctane sulfonic acid (PFOS)

PFOA and PFOS are the two major perfluoros present in North Atlantic waters. They range in concentrations from <10 to 500 pg/L. Previous work has shown that they are present in somewhat higher concentrations in near shore waters sampled around Nain (June and September 2006) and Resolute Bay (June 2006). In this sampling program we hope to obtain a detailed picture of PFOA and PFOS concentrations in near shore and open ocean sites to test our hypothesis that concentrations follow a declining gradient away from land.

Flourinated materials are found in a wide range of applications because of their unique stability toward redox agents as well as for their inert and nonadhering surface properties. They are used in many commercial products such as paints, polishes, packaging, lubricants, firefighting foams, cookware, and stain repellents. During the past six years, scientists and consumers became more aware of these materials when 3M, a longtime major manufacturer of these compounds, declared that it was stopping

production of some perfluorinated compounds, including PFOS and PFOA. The primary reason for withdrawing PFOS from the marketplace was the discovery that it is persistent, bioaccumulative, and toxic in animal studies. The U.S. Environmental Protection Agency subsequently requested more information on PFOA to ascertain the sources of human exposure and to determine the environmental effects.

PFOA and PFOS are likely present as residuals in polymers used on the ship because of past use as stain repellents, floor polishes, lubricants in Teflon (PFOA only) and therefore could be sources of contamination, especially in ship and lab air. Water was collected off the rosette through norprene and tygon tubing directly into polyethylene containers to limit contact with ship air as much as possible. Other possible sources of contamination to be avoided are Teflon tubing and bottles, Gortex or other stain repellent coated clothing, possibly KimWipes and waterproof paper.

Collection of water from the rosette for PFOS and PFOA analyses.

Between 1 and 2 L of water was pumped through 6 ml (150 mg) WAX solid phase extraction cartridges at a flow rate of 10 ml / minute using peristaltic pumps. The cartridges were preconditioned (July 18) and shipped dry in 50 ml polypropylene vials, sealed with parafilm wax. Prior to filtration, the cartridges are spiked with 50 µl of an internal standard made up of 11 PFC's. In order to avoid air contamination during filtration, an additional WAX cartridge packed with polyurethane foam was used as an air filter. After filtration, cartridges are returned to the polypropylene vials, resealed with parafilm and refrigerated at 4 C.

Filtration of water through WAX cartridge with additional cartridge acting as an air filter.

Water blanks and cartridge recovery checks were performed to identify contamination sources. As an additional check of on-board collections and extractions, duplicate water samples were collected at a number of stations. These duplicate water samples will be sent back for extraction in a clean room setting for comparison to ship extraction.

Water was collected in depth profiles using a plastic bucket for surface water and the rosette for 5, 10, 25, 50, 100 and 200 meters at 2 stations (111, 435). A spatial study was also conducted with water from 5 m (rosette collection) at 9 stations (134, 301, 302, 305, 308, 309, 310, 314, and 434).

2.8.2. Biotic Sampling (mercury, stable isotopes)

The main purpose of this study is to link physical and biological processes to mercury levels in the food web and to target the pelagic food web biomagnification and bioaccumulation of mercury with stable isotopes and fatty acids. Thus, all biological samples collected will be measured for total mercury and MeHg along with stable isotopes to place organisms into their associated trophic levels.

Biological samples were collected at every basic and full stations along the cruise transect. Various zooplankton families and fish samples were collected using the vertically towed Monster net (200 and 500 µm), an oblique Tucker net (2x500 µm) and the RMT (rectangular midwater trawl, 1600 µm). Zooplankton and fish were sorted into families, placed into plastic vials and Whirlpak bags and frozen until they can be analyzed for THg, MeHg, stable isotopes and fatty acids. Zooplankton was collected at 32 stations. Many thanks to the University of Laval zooplankton team for hard work out on the foredeck!

Additionally, total body length (the distance from the front of the head to the tip of the longest uropod) of the individuals of the hyperiid specie *Themisto sp.*, an amphipod highly distributed throughout the High Arctic was measured to the nearest 0.5 mm. Animals greater than 18 mm are considered adult and smaller than that free living juvenile. The individuals were divided into size classes; 0-10 (newly hatched individuals/Juvenile 1), 11- 15 (Juvenile 2), 16-20 (1 year old immatures), 21-30 (individuals of over 2 years old), >30 and whenever possible, separated into different vials as described above.

2.8.3. Mercury

PI: Vincent L. St. Louis (University of Alberta)
Participant: Igor Lehnherr (University of Alberta)

Introduction
Concentrations of the neurotoxin mono-methylmercury (MMHg) are increasing in many marine mammals of the Canadian Arctic to levels that may be toxic to Northern peoples consuming these animals as part of a traditional diet. The objective of our team within ArcticNet is to determine the source of this MMHg to arctic marine foodwebs and we are currently building on work completed during the previous two ArcticNet cruises (2005 and 2006). One of the key processes resulting in the contamination of biota with mercury (Hg) is the formation of methylated Hg species, such as MMHg, from inorganic Hg(II) species which themselves are not as readily bioaccumulated. The methylation of Hg(II) in marine sediments has been shown to take place in various temperate locations, and in freshwater systems it has also recently been demonstrated that Hg can be methylated to MMHg in certain regions of the water column (i.e. the hypolimnion). However, most of the research conducted thus far on Hg biogeochemical cycling in the Arctic has focused on atmospheric processes which result in the deposition of Hg(II) in marine and coastal systems; but the link from the deposition of Hg(II) to the formation of MMHg is still a missing link. Our understanding of the methylation-demethylation processes resulting in the formation and removal of MMHg in Arctic marine systems is very limited as is our knowledge of the rates of the major redox transformations that constitute the biogeochemical cycle of Hg in arctic seawater, despite the obvious importance of such information in constructing regional or global Hg models. Since a high proportion of the total Hg (THg, all forms of

Hg in a sample) measured in the lower parts of the water column during ArcticNet 2005 and 2006 existed in methylated forms such as MMHg and dimethylmercury (DMHg, a volatile, toxic form of Hg that can be photolyzed to MMHg), we hypothesize that Hg(II) can be methylated directly in the water column. In other words, we are proposing that the production of methylated Hg species in bottom sediments alone is not enough to result in the concentrations measured in the overlying water column. By adding different Hg stable-isotope tracers to seawater samples in incubation experiments, we are attempting to measure water column Hg methylation rates to determine if this process is a potential source of Hg contamination to marine organisms in the Canadian Arctic. Using the same techniques, we are also quantifying the rates of some of the other major biogeochemical processes, such as reduction and demethylation reactions, implicated in the cycling of Hg in arctic marine waters. In addition, we are also measuring background concentrations of a broad range of Hg species in the water column: THg, MMHg, DMHg and DGEM (dissolved gaseous elemental mercury) to continue building a baseline against which potential future changes in the distribution of dissolved Hg species can be compared. This work will result in the measurement of the first rate constants of some of the major biogeochemical pathways in the cycle of Hg in arctic marine waters, which will in turn provide valuable information towards building a regional Hg model. Our overall understanding of Hg cycling in the Arctic will be enhanced allowing us to better predict changes in this cycle as climate change continues to impact the Arctic.

Methods

Sample Collection and Processing:

At each station, we sampled the water column at two different depths, namely the sub-surface chlorophyll maximum and the bottom of the oxycline, using Teflon-lined Niskin bottles mounted on the ship's rosette. From each depth we collected water in separate acid-washed Teflon bottles for THg and MMHg analysis using standard ultra-clean procedures such as the "clean hands, dirty hands" protocol. THg and MMHg samples were preserved by acidification within 12 hours of collection. For the purpose of the isotope-addition methylation experiments, water was collected in certified ultra-clean amber boston-round glass bottles and 1L glass jugs by twice overfilling each bottle from the bottom – using c-flex tubing – to preserve *in situ* redox conditions. Water was also collected and filtered for sulfate and DOC analysis.

Experimental Concept and Procedure

The basic design of the methylation experiments was to add Hg(II) of a specific isotope and measure the concentration of MMHg and DMHg containing that particular isotope of Hg after various incubation times to obtain a time-series of data from which methylation rates could be calculated.

$^{198}Hg(II) \longrightarrow MM^{198}Hg + DM^{198}Hg$; methylation rate = % of ^{198}Hg added that is converted to MMHg or DMHg per day per L of water

Samples also received a spike of isotopically-labelled MMHg to monitor the decrease in that species over time from both demethylation reactions and the production of DMHg from MMHg.

$MM^{199}Hg \longrightarrow {}^{199}Hg(II)$; demethylation rate = % of $MM^{199}Hg$ lost per day $MM^{199}Hg$

$\longrightarrow DM^{199}Hg$; methylation rate = % of $MM^{199}Hg$ added that is converted to DMHg per day per L of water

Incubation samples were split into three different series for each depth. Two of these series received a received a high-level addition of $^{198}Hg(II)$ stable-isotope tracer and a low-level addition of $MM^{199}Hg$. Samples from these series were incubated in the dark at 4 °C for 0, 12 and 24 hours, after which times samples were either acidified (series 1) or frozen (series 2) to stop all biotic activity and preserve the sample. The acidification versus freezing comparison was done to ensure that acidifying samples, which is currently the protocol most often used to preserve Hg water samples, does not induce artifact methylation of the inorganic Hg(II) tracer. These samples will be analysed for $MM^{198}Hg$ and $MM^{199}Hg$ back at the University of Alberta to quantify methylation and demethylation reaction rates, respectively. The third incubation series was conducted in 1L glass jugs amended with high-level

additions of both ^{198}Hg(II) and MM^{199}Hg, and incubated for 0, 12 and 24 hours at 4 °C, in the dark. At the end of the predetermined incubation period, samples were purged with a flow of UHP nitrogen and volatile Hg species were captured by adsorption on carbo-traps (for DMHg) and gold-traps (for DGEM). This experiment will allow us to determine the rate at which DMHg is produced in the water column and if it is predominantly formed from Hg(II) or from MMHg. At the same time, we are also able to quantify the reduction of both Hg(II) and MMHg, as measured from the production of DGEM, which is the reduction end-product. At station 115, this experiment was also replicated in the presence of light to qualitatively determine whether light enhances or inhibits any of the processes resulting in the formation of volatile Hg species (DMHg and DGEM). By measuring a third isotope of Hg (i.e. one that is neither ^{198}Hg nor ^{199}Hg) during the analysis of the carbo- and gold-traps, we will also be able to measure the background ambient levels of both DMHg and DGEM in the water column.

Preliminary Results

Due to the complex analytical nature of our work, we are not able to analyze any of the samples while on board of the CCGS Amundsen. Therefore, we will not obtain any data or results until samples are returned to the *Biogeochemistry Lab* at the University of Alberta for low-level Hg analysis using various mass-spectroscopy techniques.

Stations Sampled

Station ID	Cast Number	Depths Sampled /m	Work Conducted
Station 101	004	60, 216	Full suite of samples and experiments
Station 115	011	20, 211	Full suite of samples and experiments
Station 302	025	34, 327	Full suite of samples and experiments
Station 308	029	26, 190	Full suite of samples and experiments
Station 309	031	26, 151	Ambient THg and MMHg sampling only

Station 434	036	9, 35	Ambient THg and MMHg sampling only
Station 435	046	33,125	Full suite of samples and experiments

2.9. Remotely operated vehicle (ROV) operations

Participants: Vincent Auger (ROPOS), Luc Michaud & Pascal Massot (Université Laval)

Introduction

From September 27th to October 8th, 2007 the Canadian Scientific Submersible Facility sent me, Vincent Auger, to help the University of Laval's team prepare and deploy their Sub-Atlantic Super Mohawk for its first dives as well as provide in-the-field training. Originally it was hoped that the Remotely Operated Vehicle (ROV) could be promptly setup and used to recover lost moorings. Due to time and schedule restrictions, these complex operations were however postponed to be replaced by 3 short sea-trials dives of the ROV which allowed both the ROV team and ship's crew to get familiar with the steps and considerations of operating an ROV from the CCGS Amundsen.

In retrospection, the approach taken during this expedition was essential to establish the procedures and operational familiarities required for the safe deployment and use of the ROV onboard the Amundsen. Both the Amundsen and ROV team now have a foundation to continue using their ROV and develop its potential.

Initial Preparations

On our arrival on the ship it was clear that the overall system would require 2 or 3 days of work before a dive could be attempted. The moonpool area was filled with larges boxes which would have to be moved, and the control room and ROV control equipment was partially setup. Furthermore the ROV and TMS would require extensive inspection and testing for its first dive.

The main tasks performed for preparation were:

- Emptied moonpool area of boxes and cleaned control room to allow for the setup of equipment.
- Vehicle Inspection.
- Leak found on the TMS drum shaft. The top hose clamp was slightly tightened until the leak stopped. The compensator was then filled and the leak cleaned. There is still sweating occurring at the base of the drive shaft gearbox. The base-seal should be cleaned or replaced. We did not have enough oil onboard to perform this task.
- Both TMS' compensators (2700cc each) were nearly empty. This was due to the oil slowly making its way into the tether over the course of the past months, a common occurrence in oil-compensated systems. The ROV's termination box also emptied due to the same effect. In order to avoid the unnecessary loss of oil, these compensator valves could be close when the system is not used for extended periods of time.
- Complete inspection and cleaning of the vehicle and TMS in order to verify every connection and fitting on the system.
- Test of all vehicle's functions and support systems.
- Complete setup the control room.
- Installation and test of navigation systems.
- Melting of 2-3 feet of ice which formed in the moonpool.
- By the evening of September 30th, after approximately 40 hours of work, the vehicle was fit to dive and all support systems were operational. At this point our main concern was an intermittent communication problem with the vehicle's telemetry which we were unable to pin-point.

Dives

A total of 3 dives took place during my visit. All parties involved were in agreement that if the winds exceeded 25 knots, any dive would be aborted before the sea build-up could lead to unsafe operation and recovery. Furthermore, the captain or ROV supervisor could abort a dive at any time if he/she believed the operation was unsafe. For each dive the following teams, see table 1 and 2, were established for safe launch, operation, and recovery of the vehicle.

Table 1 : Launch and recovery Team

Position	Main Tasks
ROV Supervisor	Directs the operations in the moonpool room and communicates with both the bridge and ROV control room.
Crew Supervisor	Ensures the overall safety of the operations taking place in the moonpool room.
Winch Operator	Operates the main umbilical winch under the direction of the ROV supervisor.
Crane/Cable Guide Operator	Operates the crane and then the cable guide under the direction of the ROV supervisor.
ROV Pilot	Sits at the consoles and pilots the ROV under the direction of the ROV supervisor via a hands-free telephone headset system. The pilot also reports any fault or concern to the ROV supervisor.
2 Crew	Hook and Unhook the TMS. Stabilize the vehicle and TMS while it is free hanging. Assist as directed.

Table 2: Basic Operation's Team

Position	Main Tasks
ROV Supervisor	Supervises the technical aspects of the dive
ROV Pilot	Operates the ROV under the direction of the ROV supervisor
Investigator	Guides the ROV team to achieve the scientific objectives of the dive. The investigator is often the person that has planned the dive and its objectives with the ROV team.
Winch Operator	Operates the main umbilical winch under the direction of the ROV supervisor.

Dive 1 – October 1st

This dive was designed to familiarize all involved personnel and develop operational procedures on the use of the ROV system onboard the Amundsen. As preparation for this first dive, all involved parties took part in a meeting which outlined the dive's goals, explained what was expected of each group, and also addressed any concerns on this initial operation. An important point that was raised during this meeting is that the ship does not have a bow thruster, a fact that limits the ship's ability to keep station.

Goals

- Validate all systems underwater.
- Familiarize the ROV team and ship's crew on the deployment and recovery of the system through the moonpool.
- Familiarize the ROV team with important vehicle maneuvers
- Exit the TMS
- Fly the vehicle around the TMS
- Usage of the navigation system and sonar
- Enter the TMS

Dive Log

12:30	Dive starts
	Original lifting system is unsafe - going with a strap.
	TMS lifting point is too far forward causing an unacceptable pitch.
	There is a turn in the cable leading the TMS to turn to port.
	Fit some tag lines to help control the TMS while lowering it into the water.
	At this point - decision is taken that we will not venture outside of the moon-pool due to the TMS' pitch.
	Testing that the ROV can control TMS rotations went okay. Vehicle can turn TMS with approximately 80% thrust.
	All systems are working well - no faults detected.
	Problems with Navigation system - cannot track - decision to look at this once vehicle is back on deck.
	Test with the winch to ensure that it pays in and out smoothly.
	Vehicle Recovery
14:30	Vehicle back on deck and moon-pool closed

defects

1. TMS' pitch is excessive
2. A safe TMS lifting apparatus must be built.
3. Loss of vehicle telemetry continues after 30 minutes without problems at start of dive.
4. Winch level-wind is backwards.
5. Navigation system did not track.
6. Cable guide requires a new cable – starboard winch's cable is damaged.
7. Navigation screen to the bridge, network problems.

Post-Dive Corrections

1. The umbilical lift point was moved all the way back on the lifting rail in order to reduce the pitch as much as possible.
2. Ship's engineering built an angle bracket that mount on the existing lift rail just forward of the new umbilical lift point. A lifting eye was then bolted through the bracket to allow the moonpool room's overhead crane to safely move the TMS.

3. The actual telemetry problem was found after Dive 2, a dirty fibre connection within the control console.
4. The level-wind screw was manually turned until it matched the cable's position and direction on the drum.
5. The navigation system was tested on deck, no problems were found. The system did not track during the dive as we pressed the wrong software button to "wake-up" the transponders for navigation.
6. The cable guide's starboard side winch wire was replaced and cable guide tested for proper operation. Several brackets were also grinded down to facilitate the cable guide lowering.
7. The network switch below the bridge was defective; it was replaced by the ship's electronic technician.

Dive Summary

Due to an excessive pitch angle on the TMS, the plan to venture outside of the moonpool had to be abandoned. The pitch was caused by the forward location of the umbilical attach point and was severe enough that the upper-back portion of the TMS was resting against the moonpool wall. The TMS may have pitched even further once outside the moonpool making its recovery unnecessarily difficult. Unfortunately, the lift point could not be tested prior to the dive as there is not enough headroom in the moonpool room to lift the TMS using the umbilical.

This dive however remained a good opportunity to validate all systems and identify any defects as both the TMS and ROV were fully submerged for the first time on this cruise. Once the tests done, the vehicle was recovered without problems. It is also important to note that the dive also allowed us to fine-tune our deployment and recovery procedures and manoeuvres.

Dive 2 – October 3rd

We were allotted 4 hours for this dive which picked-up on Dive 1's original goals as well as gave the ship the opportunity to practice station keeping with the TMS in the water column.

Dive Log

8:15	System is ready to dive - ship is doing a CTD
9:00	CTD is completed - ship gives okay to dive and is now drifting.
9:38	We have the TMS on top of the moonpool
10:15	Vehicle is in the water at 40 meters - going out of the TMS for flying exercises
11:15	Going back in the TMS - ship will now try to hold station
11:40	Ship is done it's station keeping test - returning to surface with the TMS
12:00	Dive is over, everything back on deck

Defects

1. Telemetry problem continues.
2. Video capture computer hangs and requires reboot.
3. Tracklink navigation system works well but periodically gives fatal error messages asking to power-cycle the transducer.

Post-Dive Corrections

1. Fibre-optic connections were moved from the -10dB to the 0dB connectors. Cleaned all fibres, including ones inside of console. We can no longer reproduce the telemetry problem.
2. The video capture computer also ran the Tracklink software; we separated the two and did several successful capture tests.
3. We could not reproduce this behaviour, maybe (2) was also causing problems with the Tracklink software.

Dive Summary

All dives objectives were reached. The deck crew was confident and both the deployment and recovery were smooth. Luc and Pascal practiced flying around the TMS and were able to familiarize

themselves on the Super Mohawk's particular flying dynamic. Luc also practiced flying from the TMS's camera and successfully "parked" the vehicle back in the TMS.
Once the ROV was back in the TMS, the ship practiced station keeping for approximately half an hour. Establishing the ship's ability to keep station is essential to successful ROV operations. The captain was able to gain valuable information on the drag behaviour of the TMS during these manoeuvres. As we expected, the TMS essentially remained directly below the moonpool during the entire dive but abrupt ship motion could cause steep cable angles.

Dive 3 – October 6th
This final training dive was designed to mimic a video exploration dive. 4 hours were available for this opportunistic dive which had us sheltered from foul weather in Admiralty Inlet. After our departure from the Nanisivik port, a dive area was specifically selected for its flat muddy bottom (300m depth) which would facilitate bottom exploration as well as minimize the risk of a TMS collision with rising subsea features should the ship have problem holding station.

Goals
- Familiarize the night crew with the deployment and recovery procedures
- Provide more flying practice around the TMS.
- Safely bring the system to the bottom, only if the ship can hold station.
- Explore a small area and do a short transect if time allows.
- Return to the TMS from the bottom and safely enter TMS.

Dive Log

21:00	System is ready to dive – ship is drifting.
	Lowering TMS through moonpool and stopping TMS at 30m depth – ship is free to manoeuvre.
	Vehicle exits the TMS – fair currents make it difficult to keep TMS in sight.
	Lost sight of TMS for approximately 10 minutes
	Found TMS again, several turns in the tether from the search. Found out that the trim buttons were both pressed causing the vehicle to behave abnormally hence making the search for the TMS harder than it had to be.
	Took out the turns (~8) in the tether.
	Lowering TMS at 20m/min while Pascal is flying around it.
	TMS near bottom ~ 40m according to ship's echo sounders.
	Luc flies the vehicle to the bottom, slowly going away from the TMS' mouth.
	Vehicle is on bottom at 311 meters – exploring and practicing landings and transects in soft mud.
	Compass cannot be used – navigation system is reliable enough to work.
	Vehicle returns to the TMS.
	Pascal practices flying in the TMS camera and parks the vehicle.
	Beginning recovery at 25m/min
23:45	Vehicle is back on deck

DEFECTS
1. Video capture computer crashed during the dives – computer completely hangs and requires reboot.
2. Tracklink software still hangs and gives an error message asking for a transducer power-cycle.

Post-Dive Corrections
1. The captured video was corrupted during the computer crash. Considerable effort was put into piecing together the corrupted file in order to extract some of the video. While we were able to recover some of the video, the capture software had other problems and the original data was

corrupted. Some video snippets and images were however recovered. It may be possible to recover more of the video and images but is likely not worth the effort. Pascal will look into the capture card problem, the last hints pointed towards an IRQ conflict.

2. The Tracklink software "crashed" several times. While it was easy and relatively quick to get going again the problem was an annoyance. This matter should be discussed with LinkQuest Inc.

Dive Summary
All of the dive's objectives were reached and the vehicle explored a bottom crawling with life. The night's crew first deployment was smooth and without incident, the ship held station beautifully never venturing outside of the watch circle, and both Pascal and Luc were able to widen their piloting skill sets.
The main hick-up during the dive was the lost-of-sight of the TMS shortly after the vehicle's exit. While there was a considerable current, I believe the accidental enabling of the *trim* buttons was the main cause of this problem. The *trim* buttons are used to apply a constant vehicle attitude to offset surrounding currents, a useful feature when you've enabled it on purpose. The excessive *trim* easily simulated a stronger current and greatly reduced the vehicle's maneuverability leading to the loss-of-sight of the TMS. The TMS was however in-sight after approximately 10 minutes and while there was some turns in the tether they were all taken out and offered a improvised tutorial on a situation both Luc and Pascal will face again.

With approximately 30 minutes of bottom time, both Luc and Pascal were able to pilot the vehicle on the bottom and practice soft landings and travels. The ability to travel without suspending sediments is an important skill as good video and exploration depend on it. It is also important to note that the vehicle's compass does not work well enough to rely on. The turn counter, a useful tool which tells you how many turns you've put into the tether, uses the compass and can therefore not be trusted. During our bottom exploration we were careful to offset each right turn with a left turn, a good habit in any case.

On our return to the cage, we were especially careful when paying-in as if there was a turn in the tether it could have easily got caught in the TMS and caused damage leading to loss of vehicle telemetry, etc. The tether did not have any turns and we were able to return the vehicle in the TMS without problem to begin recovery.

Observations and Recommendations
During the preparations it became evident that the University of Laval's technicians have a wide range of responsibility and tasks to perform on the vessel. While they were able to offer some help during the system preparation their many responsibility made it difficult to dedicate as much time to the ROV as they would want or would be required if the system was used frequently.

The Super Mohawk system is a good vehicle with great potential but it is important to remember that the Amundsen operation is just beginning and will require some supplies and tools. During my visit I compiled a list of concerns and things to do in order to make the vehicle a reliable tool to the users of the Amundsen. The "must" points that are to follow are things and items the vehicle and team require.

Must do

- Starboard vertical propeller blade needs to be resurfaced. It is damaged and likely unbalanced. This unbalance will cause unnecessary strain on the propellers shaft and possibly reduce its lifespan.
- The TMS slip-ring torque arrester is secured to the TMS drive motor electrical cable and connector and not a fixed bracket as shown in the slip-ring's user manual. While this came from the factory this way, a proper torque arrester bracket should be built and installed to remove the unnecessary strain on both the oil-filled hose and drive motor electoral connection.
- Leak in the port arm's wrist cylinder. This problem was known but we had too little hydraulic oil (Tellus 22) to perform this task without risking our ability to dive the vehicle.

- Contact Sub-Atlantic concerning the radio interference problems on the pilot's console. They have likely seen and fixed this problem before.
- Contact LinkQuest concerning the constant power-cycle that must be performed on the transducer during operation.
- Organize spare and establish any missing critical spares.
- Establish any missing tools or instruments required for the proper offshore maintenance of the vehicle.
- Refit the TMS drive gear housing. It is slowly leaking oil from the base-seal.

Must Buy

- Fibre-optic kit which will allow the team to perform vehicle re-termination.
- Fibre-optic light meters to troubleshoot communication problems.
- Fibre-optic spare connectors and patch cables.
- Vehicle oil-supply of all 3 necessary oil. Tellus 22, Castrol Hyspin, and Transformer oil.
- Hydraulic fittings, valves, hoses, etc…
- Compensation bottles and nozzles, at least 2 more.
- Spare set of FOCAL multiplexer board (top and bottom).

ROV Suggestions

- Install altimeter on the TMS. This is almost "must" items as it will help keep the TMS at a safe distance from the bottom. Dragging the TMS on the bottom can have catastrophic consequences.
- Install a radio and strobe beacon on the vehicle. Should the vehicle be separated from the TMS for any reason, these beacons will be invaluable in finding the vehicle again.
- Install a camera on the cable guide. This isn't necessary but would be a great addition as it would allow the ROV pilot to guide the vehicle in the moonpool more efficiently than with only the supervisor's commands.
- Flush all vehicle oils. This is a good thing to do for oil that has been sitting for over 3 years.
- Switch both cameras internal with NTSC cameras. The FOCAL multiplexer boards will handle NTSC and this would remove a layer or complexity to the system. Keeping the housing and changing only the electronics will also be much cheaper than changing the entire camera.
- Look at important non-critical spares for vehicle's support systems. Navigation and video are currently the vehicle's only deliverable for scientific mission, if these missions are to be successful spares for these support systems should be available.
- Build a sturdier pole for the Tracklink system to reduce vibration.
- Add spare fibres from the winch to the control room - having these fibres in protective coating would also be beneficial against abrasion.

General Suggestions

- Investigate usage of ship's Dynamic Positioning system for ROV operations.
- Prepare future moorings with an ROV in mind. Insert a weak leak the ROV will be able to manipulate or cut free.
- Consider a user-pay usage or other revenue system for ROV missions.
- Consider marketing of the ROV's capabilities to other science groups.
- Think of ways to extend vehicles capability while considering the moonpool limitations.

Conclusion

The University of Laval Super Mohawk is a system with great potential. It is however important to keep in mind that it is in its infancy and that both the ROV team and the Amundsen crew need to continually develop and practice their skills in order to competently handle problematic situations and successfully complete complex missions such as mooring salvage and scientific sampling.

For the ROV team, it would be beneficial to continue a partnership with CSSF which can help with advice and mission planning as well as provide further training and assistance during offshore missions. The University of Laval's ROV team is often very busy with other responsibility and the helping hand of an experienced ROV pilot has already proven valuable.

The CGSS Amundsen did very well during my visit. The ship was able to hold station without the use of a dynamic positioning (DP) or bow thruster. While the ship does have DP, mechanical problems did not allow us to use it. Dynamic positioning or a bow thruster would be extremely beneficial to ROV operations under less-than-perfect weather conditions.

The future uses of the ROV are unclear at the moment. It is certain to eventually serve as a tool in mooring salvage as well as seafloor exploration. There has also been some interest in its use to inspect the ship's hull and propellers for damage, a task performed by ROVs on other icebreakers to plan dry dock repairs. Regardless of the short-term work plans, I believe it is important for both the ROV team and the Amundsen crew to continue using the ROV on a periodic basis. Not only will this improve the team's performance and skill, it will ensure that the vehicle and team are ready to dive when called upon

Leg 4

8 November – 20 December 2007

edited and compiled by Gary Stern and David Barber
(Chief Scientists)

2. Team reports

2.1. Team 1

2.1.1. CTD/Rosette

Participants: Hugo Drouin, Marie-Emmanuelle Rail (INRS-ETE, 490, Rue de la Couronne, Québec)

Objectives
Description of water masses and general circulation over a year in Beaufort Sea and Amundsen Gulf.

Materials
Physical parameters were recorded using a ship mounted RDInstruments Ocean Surveyor ADCP (150kHz), and a rosette frame equipped with 24 bottles of 12 L and the following sensors:

Table 1: Sensors used on the Rosette

Photo	Item	Manufacturer	Type & Properties	Serial Number
	CTD	SeaBird	SBE-911 Sampling rate : 24 Hz	
	Temperature	SeaBird	SBE 3plus Range: -5°C to + 35°C Accuracy: 0.001	4204
	Pressure	SeaBird	Accuracy: 0.015% of full range	90584
	Conductivity	SeaBird	SBE 4C Range: 0 to 7 S/m Accuracy: 0.0003	2696
	Oxygen	SeaBird	SBE-43 Range: 120% of saturation Accuracy: 2% of saturation	0427

	pH	SeaBird	SBE-18 Range: 0 to 14 pH Accuracy: 0.01 pH	0444
	Nitrates	Satlantic	MBARI ISUS Range: 0.5 to 200 µM Accuracy: ± 2 µM	134
	PAR	Biospherical		4664
	SPAR	Biospherical		20147
	Fluorometer	Sea Point		2465
	Transmisometer	WetLab	Path length: 25 cm	CST-558DR
	Altimeter	Benthos		1061

Method

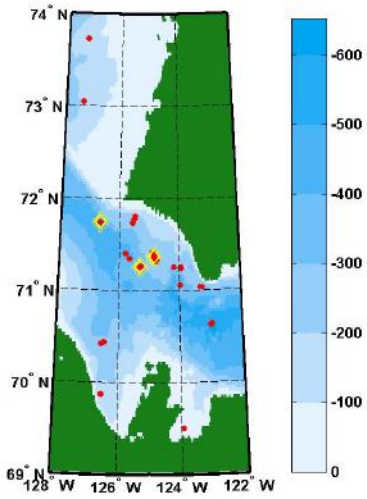
For the whole leg, because of heavy ice conditions, the rosette was deployed from the Moon Pool. CTD or Rosette casts were usually performed twice a day at 6-7 a.m. and 6-7p.m. Three times, we did a 13 hours non-stop CTD sampling. Water was sampled according to each team requests. Here are examples of usual depths collected by them.

- *Nutrients* (Team 7; PI: Jean-Éric Tremblay): salinity of 33.1, 10, 20, 30, 40, 50, 60, 80, 100, 120, 140, 160, 180, 200, 250, 300 and every 100 m up to the bottom.
- *DIC* (Team 6; PI: Lisa Miller): salinity of 33.1, 10, 20, 30, 40, 50, 60, 80, 100, 120, 140, 160, 180, 200, 250, 300 and every 100 m up to the bottom.
- *Contaminants* (Team 8; PI: Gary Stern): 10, 25, 50, 100, 200 m and bottom.
- *DNA* (Team 7; PI: Connie Lovejoy)
- *Microbes* (Team 7; PIs: Carlos Pedros and Roxanne Maranger)

Sampling field

We focus on the Amundsen Gulf and on western part on Banks Island. Because of some problems, the hull ADCP recorded only the first two weeks and the last five days.

Figure 1: Positions of Rosette casts are shown as red dots and stations of 13 hours sampling are yellow diamonds



Probes calibration

Salinity: Samples were taken on many casts with small bottles of 200 mL. They were analysed with an autosal GuildLine, model 8400B. Its range goes from 0.005 to 42 and its accuracy is <0.002. The results were satisfying. The difference in between the salinity probe recordings and the samples was around 0.025.

Oxygen: Oxygen sensor calibration was performed using Winkler's method and a Mettler Toledo titration machine.

pH: Tests were done three times using two buffers. The sensor is quit stable. Results are as follow:
Buffer 4.01 gave 4.02
Buffer 7.00 gave 7.41
Sea water is usually around pH=8, we can expect pH data to be a little over estimated.

Reagent Blanks were performed once, results show that chemicals are still good (m<4). We sampled oxygen on six casts.
Each time, we choose five depths of different oxygen concentration and sampled it three times. Results were really goods, the probe recordings and the samples were always quite similar.

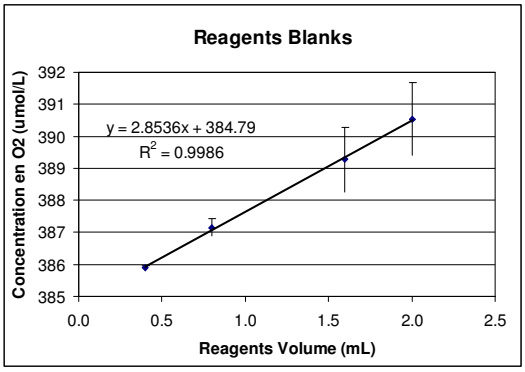


Figure 2: Reagents Blanks (m=2.85).

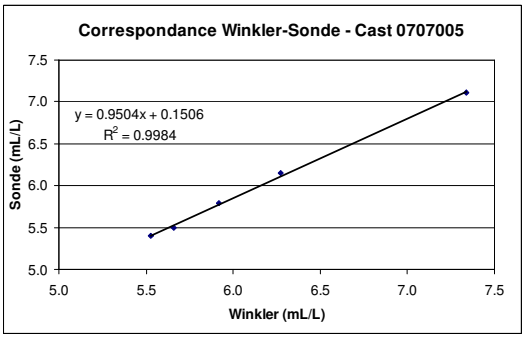

Figure 3: Relation between samples and probe recordings during cast #005 (m=0.95).

Problems

- **Sensors**
  Water got into electronic cables a few time sending an error signal to the computer. Very few data are lost, mainly on casts 084 and 101. Every sensor works well except the nitrate one. The nitrate profiles always looks the same, but the data range change often.
- **Bottles**
  We got no problem with the bottles on this cruise, except when they leak a little. We changed the bungee ropes and the O rings on most of them but they keep leaking.
- **Deck material (winch, A-frame, etc.)**
  The cable guides broke often. The winch got no problem.
- **ADCP:** we lost the GPS data for a week or two. We lost the hard drive after three weeks. We couldn't sample on the fifth week because of heavy ice under the ship hull affecting signal.

Available data

All information concerning the Rosette casts are summarized in the CTD Logbook. It includes cast and station numbers, date and time of sampling in UTC, latitude and longitude, bottom and cast depth, comments concerning the cast and its name. A Rosette sheet was also created for every single cast. It includes the same information than the CTD Logbook plus the bottle distribution among every sampling team. The weather information is written in every Rosette Log as well as in a meteorological logbook. For every cast, data recorded at the moment of bottle closure were averaged and recorded in the so-called 'bottle files'. Averaged data are those recorded between 3 seconds before bottle closure and 7 seconds after it. It includes the bottle position, time and date, pressure, temperature, salinity, transmissivity, chlorophyll, oxygen, irradiance and pH measurements. All those files are available on the 'Shares'.

- Rosette sheets and the CTD logbook : Shares\Leg4\Rosette\logs
- Bottles files : Shares\Leg4\Rosette\bottles
- Plots of every cast including salinity, temperature, oxygen, transmissometer, nutrients, fluorometer and irradiance : Shares\Leg4\Rosette\plots

Between November 8th and December 20th 2007, 105 casts were performed.

Preliminary Results

The 13 hours marathons were performed on two locations. The first was done on station 2007-D5 and the two others on station 2007-D7.

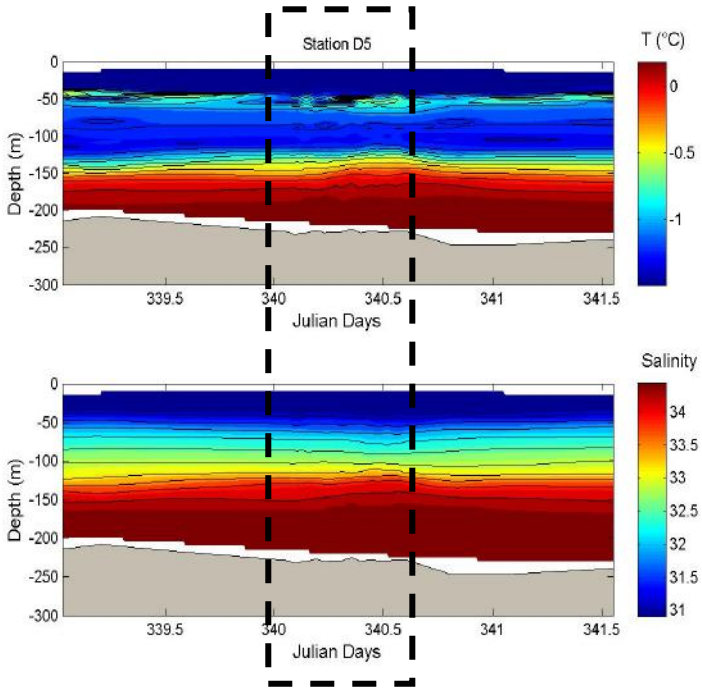

Figure 4 show temperature and salinity data recorded on station 2007-D5.

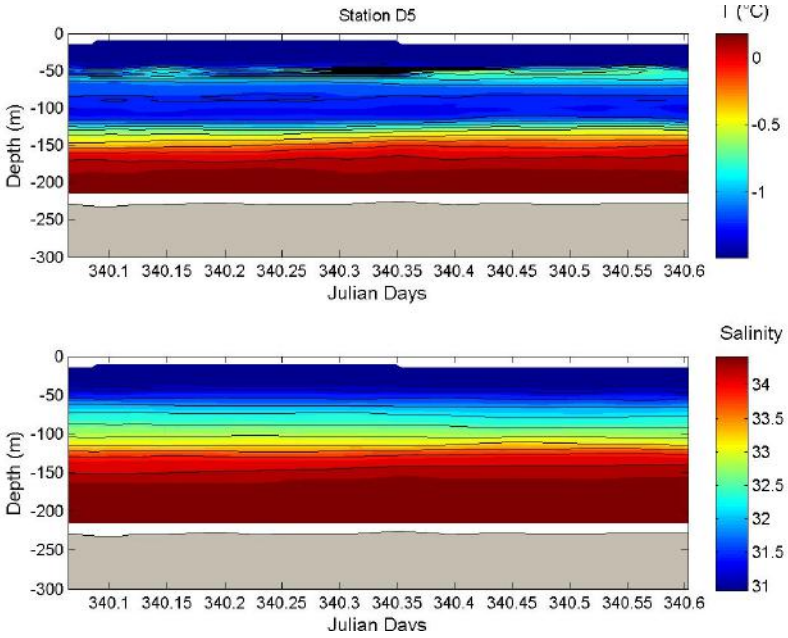

Figure 5 is a zoom on the 13 hours sampling on this same station (2007-D5).

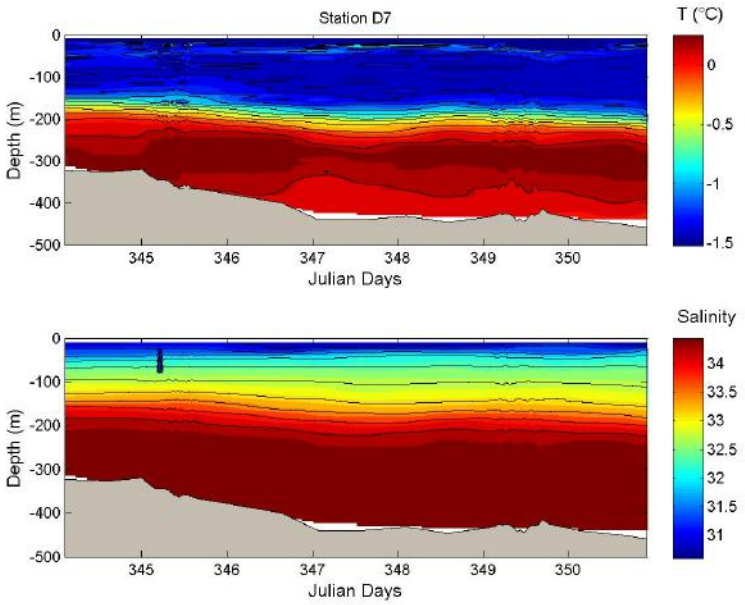

Figure 6 show temperature and salinity data recorded on station 2007-D7.

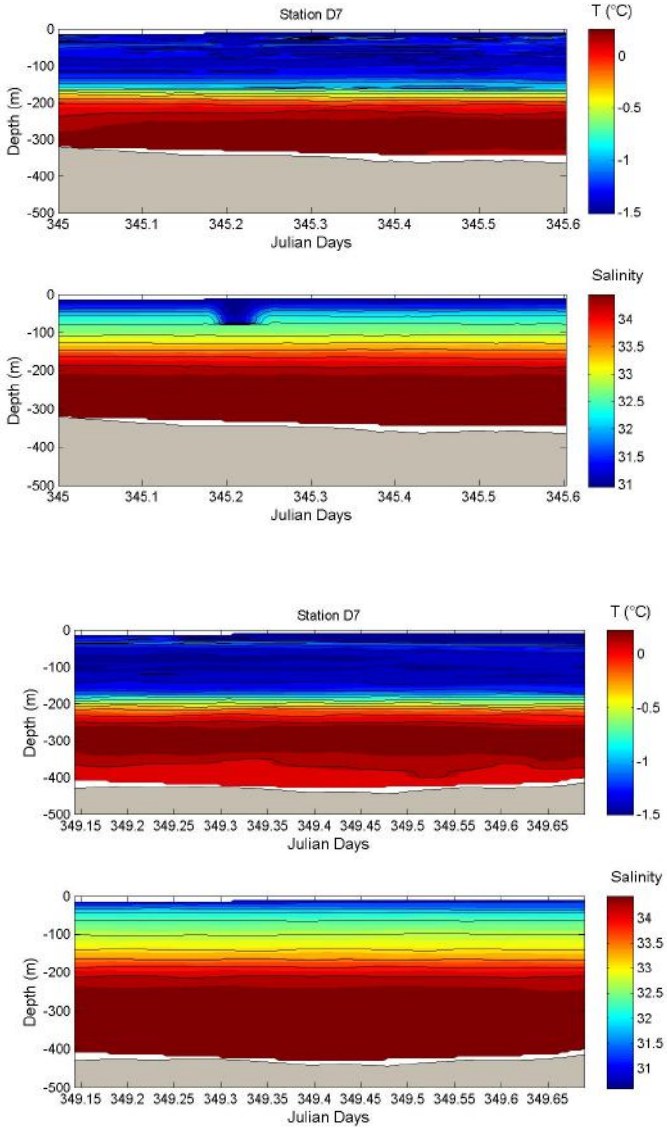
Figure 7 and **figure 8** are zooms of the two 13 hours sampling of this station (2007-D7).



2.1.2. Turbulence

Participant: Daniel Bourgault, *Memorial University*

Introduction and objectives
Ocean turbulence act to mix water properties, such as heat, salt, nutrients, pollutants etc. In order to understand and predict the evolution of ocean properties at all time-scales, from weather to climate time-scale, we need to understand how these constituents get mixed given the background (e.g. stratification) and forcing conditions (winds, tides).

The objective is to collect *in situ* measurements to quantify ocean mixing in the Beaufort Sea and Amundsen Gulf.

Instrument and installation
The Vertical Microstructure Profiler (VMP) is a loosely-tethered free-fall profiler. It is equipped with a suite of microstructure sensors that can measure mm-scale water properties from which the

turbulence intensity can be inferred. These sensors are: 2 shear probes, 2 microstructure thermistors and 1 microstructure conductivity sensor. The VMP is also equipped with standard SeaBird temperature and un-pumped conductivity sensors.

The VMP was deployed from the moonpool. A dedicated space and a table was made in the moopool area, on the other side of the rosette, for the VMP deck unit and winch (see photo below).

Figure 1: VMP installation in the moonpool area.

Sampling Protocol
The sampling protocol established for the VMP can be divided into two categories:

Monitoring mode: The long-term monitoring mode of the VMP operations consists in sampling continuously for one hour twice a day, once in the morning, generally at around 0700 or 0800, and once in the evening, at around 1900 or 2000. Around 3-5 profiles can generally be collected per sampling period, depending on the depth. We hope this sampling strategy will be continued in the following legs in order to obtain a long time-series over the winter season of the water properties and turbulence characteristics within the CFL drift site.

Experiment mode: The experiment mode of sampling is carried out on an opportunistic basis. The type of experiment carried out depended on the person in charge of the VMP and should be pre-arranged with the Chief Scientist. Examples of experiments that could be carried are: Sampling before, during and after a strong wind event or sampling through a newly formed flaw lead. Another example of experiment, as done twice during Leg 4, is to look at the semi-diurnal variability by continuously sampling for a period of 13 hours.

Sampling stations and data management
Around 250 VMP profiles were collected during Leg 4. All the information relative to each profile, such as position, depth, number of profiles collected, atmospheric conditions, etc., is logged into the Excel file: **LogBook_CFL_Leg4.xls**

All data are stored on the VMP laptop and a backup copy is stored on D. Bourgault's personal laptop.

The table below summarizes the sampling carried out during Leg 4:

Date (2007), Time	Lat	Lon
16 NOV, 1107	69 52.111	-126 30.056

16 DEC, 2254	71 28.691	-126 19.403
18 DEC,1517	71 46.374	-125 57.347

Observations

Figure 1 shows typical profiles of temperature, salinity and microstructure shear obtained with the VMP. In general, the top 50-m is characterized with finescale temperature and salinity structures. The measured shear is often quite uniform from surface to bottom. More detailed analysis are required to infer turbulent quantities from these measurements.

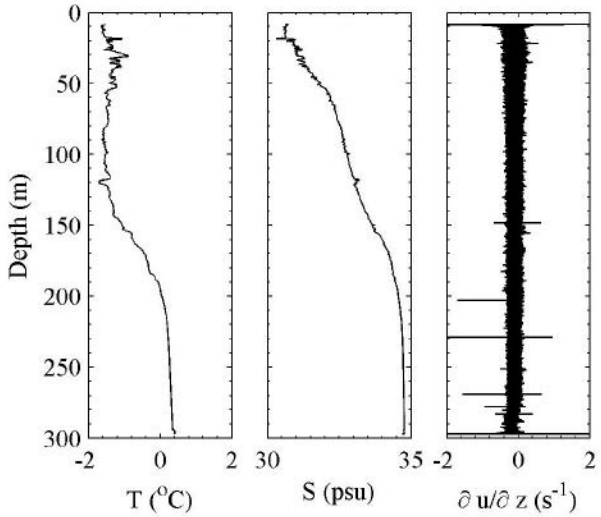

Figure 2: Example of raw temperature, salinity and micro-shear profiles obtained with the VMP on the 10 December 2007.

Figure 2 shows an example of measurements collected during one experiment where continuous VMP profiles were collected for 13 hours. 56 profiles were collected. The figure shows the temperature variability observed during the sampling period. There is no clear evidence that tides induced important change, although inspection of the ADCP data will be necessary to confirm this. Large variabilities in temperature, ±0.5 °C, were observed for the layer located between 40 m and 80 m.

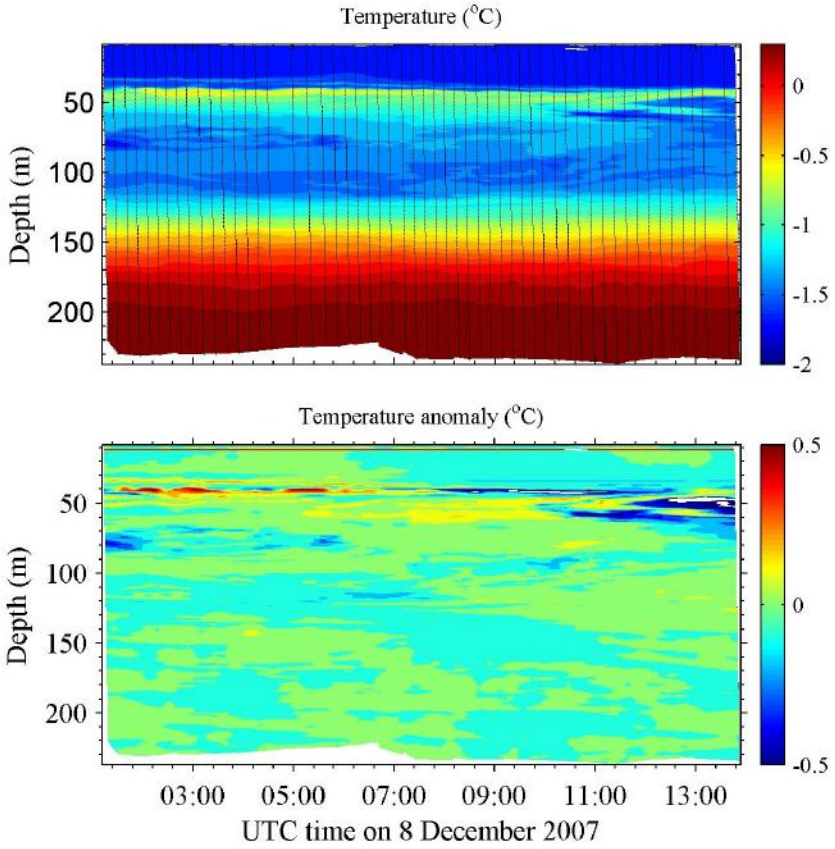

Figure 3: Example of measurements obtained during one of the VMP tidal-variability experiment. (top) temperature field and (bottom) temperature anomaly highlighting the variation over the course of the sampling period. The oblique vertical lines in the top panel represent the VMP casts.

Problems

One of the shear probe channel (channel S2) does not work. The problem is likely due to the small white cable (called SMC cable) that connects the sensor to the inside electronics. D. Bourgault ordered new shear probes and new cables. These will be brought on the ship by G. Sutherland on Leg 5. The SMC cable for shear probe 2 should be replaced as soon as possible.

Since the SeaBird conductivity sensor is not pumped this sometime caused spurious, unrealistic spikes in conductivity when the probe goes through strong temperature gradients. This is a well-known problem for conductivity cell and relates to the thermal lag of the cell. These measurements will have to be taken with care. Methods exist to remove this problem (papers from R. Lueck. Ask D. Bourgault).

Otherwise the instrument seems to work fine. It is important to regularly clean the probe connectors with contact cleaner.

2.2. Team 2

2.2.1. Ice dynamics

PI: David Barber
Cruise Participants: Monika Pucko, Phil B. J. Hwang, Mukesh Gupta, Dustin Isleifson, Matthew Asplin, Jinping Zhao, Tao Li

General Ice Conditions
During Leg 4A we encountered many different forms of ice, including nilas, thin first year ice, and multiyear ice. The most common type of ice encountered was first year ice around 40 cm thick with frost flower coverage. In Leg 4B we began to visit thicker first year ice, up to a thickness of about 80 cm at most. Snow cover was generally not present, with the exception of the multiyear ice case and a few others.

Physical Sampling
The ice raid program that was started in Leg 3B was maintained throughout Leg 4A. The goal is to obtain physical and microstructure measurements of the snow and sea ice. We generally used the ice cage on the port side of the ship, but several times we visited the ice by skippyboat in order to visit several sites of interest or to simply get away from the ship influence. In Leg 4B we reached the drift mode of the CFL project and therefore we were able to visit the site regularly via the gangplank on the ship. At this point in time it was critical to set up a fence around the EM measurement location such that it would not be accidentally disturbed.

The ice surface condition was recorded and site photos were taken. Our standard procedure was to take photos with a metre-stick present in order to obtain information on the surface conditions, and when appropriate the percentage distribution of frost flowers and their type. When snow was present we performed a snow pit measurement according to our standard procedure. This includes temperature profiles, salinity profiles, capacitance plate measurements, and snow grain photos. Two ice cores were taken at each site – one for temperature, one for salinity and microstructure. Microstructure analysis was performed on at least the top 20 cm of the ice core, and in most cases, the entire core was analyzed. For salinity we cut the cores into 5 cm segments and allowed the segments to melt in a plastic bag or container. The conductivity, temperature, and salinity were recorded using a conductivity meter.

The cold lab temperature was regularly maintained throughout Leg 4. We found that it was useful to have a day every ~10 days during which the cold lab was heated in order to defrost the condenser on the cooling unit. Otherwise, the temperature eventually will not be consistent and will slowly rise, as in Leg 3.

21 different sites were visited throughout the project. Once we were in the drift station we visited the ice each day to observe the diurnal variability. The ice raids are summarized in Table 1.

Table 1: Ice raid summary.

DATE	STATION	TIME	ICE TYPE	ICE MICRO
15-Nov-07	1117	20h00	First year ice (33 cm)	No
16-Nov-07	1117	11h00	First year ice (35 cm)	Yes
18-Nov-07	405	16h00	FYI with frost flowers (43 cm)	Yes
19-Nov-07	405	03h00	FYI with frost flowers, finger rafting of ice (46 cm)	Yes

19-Nov-07	1100	19h00	Rubble ice, FYI (46 cm)	No
20-Nov-07	1200	10h00	Consolidated pancake ice (6 cm)	Yes
20-Nov-07	1910	19h30	FYI with frost flowers (37 cm)	No
21-Nov-07 & 22-Nov-07	437	21h30 & 11h30	FYI with frost flowers (56 cm)	Yes
24-Nov-07	1825	16h00	MYI with snow (>3.2 m)	Yes
24-Nov-07	1820	21h00	FYI with frost flowers (26 cm)	Yes
25-Nov-07	1812	18h00	FYI with frost flowers (31 cm)	Yes
26-Nov-07	1800	10h00	FYI with frost flowers (24 cm)	No
26-Nov-07	1800	12h00	Nilas (9 cm)	No

28-Nov-07	2007D1	09h00	FYI (52 cm)	Yes
29-Nov-07	2007D3	18h00	Nilas (4 cm)	Yes
2-Dec-07	2007D4	11h00 & 23h00	FYI with frost flowers (33 cm)	Yes
4-Dec-07	2007D5	14h00	FYI, old consolidated pancake (26 cm)	Yes
9-Dec-07	2007D6	10h30 & 13h30	FYI with thin snow (69 cm)	Yes
10-Dec-07	2007D7	13h00	FYI with thin snow (78 cm)	Yes
17-Dec-07	2007D8	18h45	FYI with thin snow (48 cm)	Yes

Ship Based EM Measurements

EM measurements were conducted throughout Leg 4 in order to observe the interaction of electromagnetic radiation with various ice conditions. The collected data will be used in electromagnetic modeling studies and for calibration of satellite remote sensing data. The results of this study will allow for us to improve our knowledge of the temporal evolution of sea ice physical, thermodynamic, and electrical properties during the fall freeze-up period.

Scatterometer

A fully polarimetric scatterometer system was operated at each station stop. Initially the height was recorded at 7.56 m above the surface, but later this value changed due to loading in the ship and adjustments of the instrument to a height of 8.2 m. Measurements from the ship were conducted with a sweep from -30° to 30° in the azimuth, requiring the 0° reference at a perpendicular line to the ship side. The variation in elevation was measured with sweeps in the elevation at 5° increments on the range 20° to 60°. An infrared transducer (Everest, 4000L) was mounted on a rail near the scatterometer. The ice thickness camera was moved from the main deck on the port side to the scatterometer shed, one deck higher. This was due to issues with location and heating of the controlling laptop.

Ship-Based Radiometer (SBR)

Dual polarized radiometers operating at 37 GHz and 89 GHz with a 6° were mounted about 12 m above the sea surface on the port side of the ship. During transect operation the radiometers were kept at an incident angle of 55°. At station stops the system was operated in a scan mode, changing the incident angle from 30° to 150° using 5° steps. A network camera was used to monitor the surface conditions at a sampling rate of 10 s. The settings have not been changed otherwise. In addition, a

hand-held camera is used at each site to provide more information on the surface conditions.

Laser Profiler
A laser profiler was used to investigate the surface roughness during EM transects, but saw little use during Leg 4B due to temperature restrictions and breakage of the beam mount.

Ground Penetrating Radar
A ground penetrating radar system (GPR) was used to investigate snow and sea ice thickness and structure on an opportunistic basis. Three separate units were operated with frequencies of 250 MHz, 500 MHz, 1 GHz. Operation of these units at this time of year is new for our group, so everything was very experimental. We found that we were unable to obtain useful results until the ice was at least 60 cm thick. Unfortunately, due to corrosion and sensitivity the connectors on two of the units were damaged (500 MHz and 1 GHz units) and must be replaced. As well, the odometer began to malfunction for no apparent reason. These replacements are expected to be on the ship for Leg 5B or 6B at worst. One of the useful results we had from this experiment was the measurement of the runway thickness using the 1 GHz units. We found that we were able to validate the thickness of each runway and used several auger holes to acquire the correct thickness of approximately 78 cm at each end of the GPR transect.

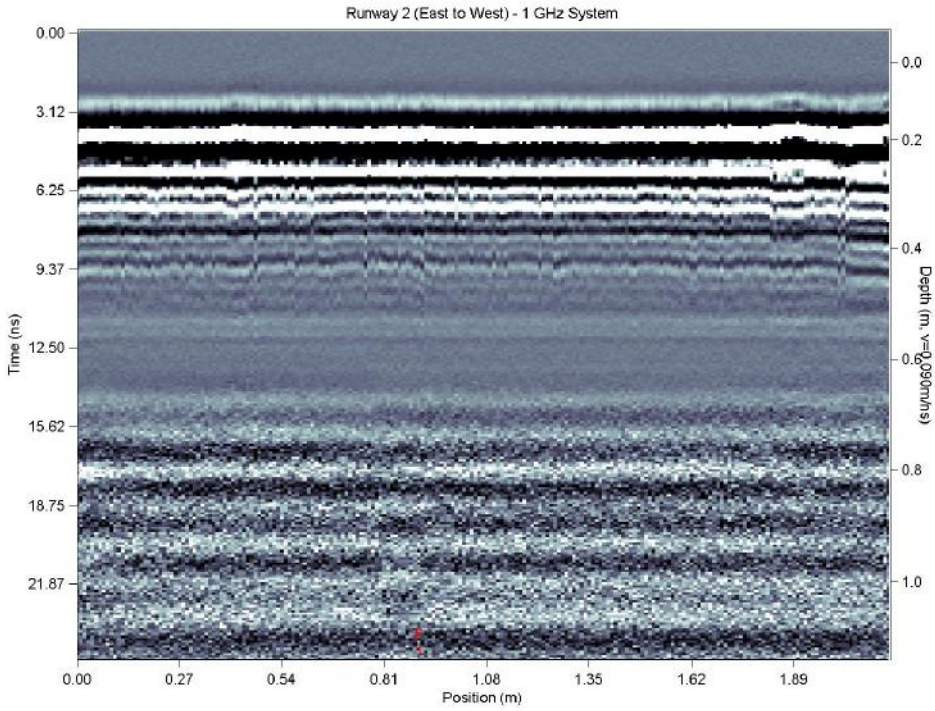

Figure 1: Successful GPR profile of the runway at Station 2007D7

Skippyboat
The purpose of the skippyboat is to allow us to investigate several sites using the ship based EM equipment, and still return to the sites to perform physical sampling. The skippyboat was deployed several times over the course of Leg 4. There were no significant issues that arose during operation. Currently the skippyboat has been winterized until a later date when it is more appropriate to use it.

Atmospheric Sampling Program
The purpose of the atmospheric sampling program is to monitor cloud cover and cloud properties, upper level and boundary layer winds, temperature, and humidity.

All-Sky Camera
The all-sky camera system is used to take pictures of sky in order that percentage and type of cloud cover may be determined throughout the cruise. The all-sky camera was non-functional upon our

arrival onboard the ship. We discovered that the webcam required a laptop with a USB 2.0 port in order to obtain high-resolution pictures, and so, a new laptop was obtained. There were ongoing issues heating the webcam itself; it would cease operating at temperatures below -5 C. The ship's electrician was able to construct a small, custom heater out of electrical "heating wire." The all-sky camera is now fully functional, and requires daily maintenance to ensure the dome is not frosty.

Ceilometer

The ceilometer is used to measure the height of the cloud layers above the ship. The ceilometer was fully functional throughout all of Leg 4. Routine maintenance and backup was performed at regular intervals.

Profiling Radiometer

The profiling radiometer is used to measure the temperature, relative humidity, and pressure within the atmosphere. It was activated fully on November 22, and has been running for all of Leg 4B. A liquid nitrogen calibration was conducted on November 26, and will be performed again during Leg 6. The instrument has collected data on the standard high pressure inversions that are characteristic of this region, as well as boundary layer temperature and humidity profiles. The passage of a significant low pressure system was profiled Dec 13/14.

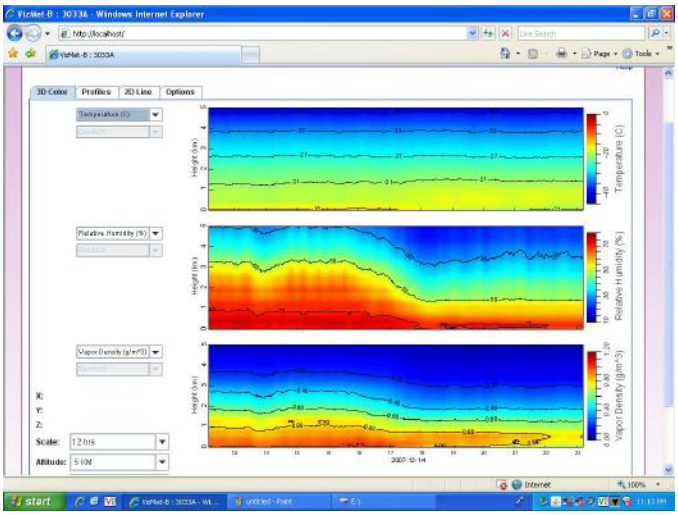

Figure 2: Profiling radiometer graph showing changes in temperature, relative humidity, and water vapour density throughout the atmospheric column associated with the passage of a cold front on December 14th.

Radiosondes (weather balloons)

The radiosonde system setup was delayed by bad weather; balloon launches were very difficult to conduct during Leg 4A. There were 14 balloon launches during Leg 4B, including a coordinated 7-balloon launch over 36-hours at a 6-hour interval, which profiled the passage of the Dec 13/14th cyclone (2007D7). Other launches were performed Dec 1st (Sach's Harbour), Dec 2nd - 3rd (2007D4), Dec 12th and Dec 15th (2007D7). Two launches were unsuccessful.

Laser Precipitation Gauge

This instrument was fully functional throughout Leg 4. The instrument continues to run, and all data has been downloaded and archived.

Ice Motion Beacons

We were able to deploy many ice beacons during Leg 4, and future deployments will be at approximately 2 week intervals or as significant opportunities arise (MYI floes).

Table 2: Ice motion beacon deployments.

Beacon ID	Date Deployed	Location Deployed	Status
18300	Nov 19 2007	MYI: De Salis Bay	ACTIVE
17300	Nov 22 2007	FYI: Stn 437	LOST

23330	Nov 24 2007	~74N, 127W	ACTIVE
912920	Nov 24 2007	Stn 1825	ACTIVE
13320	Nov 24 2007	Stn 1825	ACTIVE
24220	Dec 8 2007	Stn 2007D6	ACTIVE
22250	Dec 14 2007	MYI near 2007D7	ACTIVE
918920	Dec 16 2007	MYI near 2007D7	ACTIVE

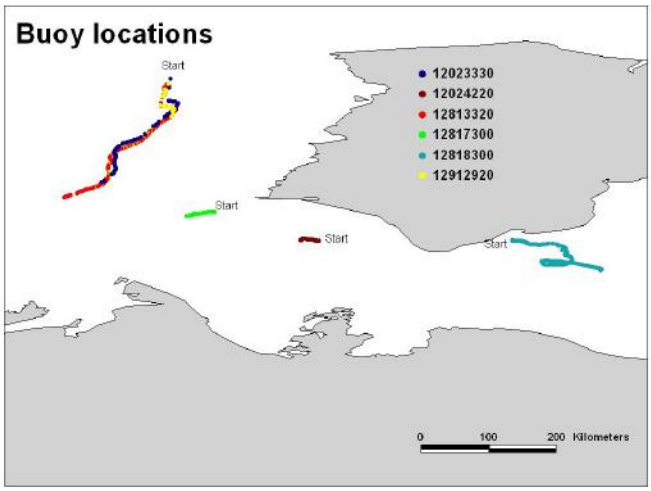

Figure 3: Ice beacon locations as of December 14, 2007.

Met-ocean "MOBS" Buoys
MOBS buoy deployment was limited to testing and buoy locator system testing. The functionality of the buoy's range-finding system appeared to be limited to only 500-700m (contrary to the company's specifications). The solution devised was to use the ship's FM transceiver set to 160.725 MHz, and attach a battery-powered strobe light to the beacon. No data collection occurred due to the lack of opportunities for safe deployment and recovery in open water.

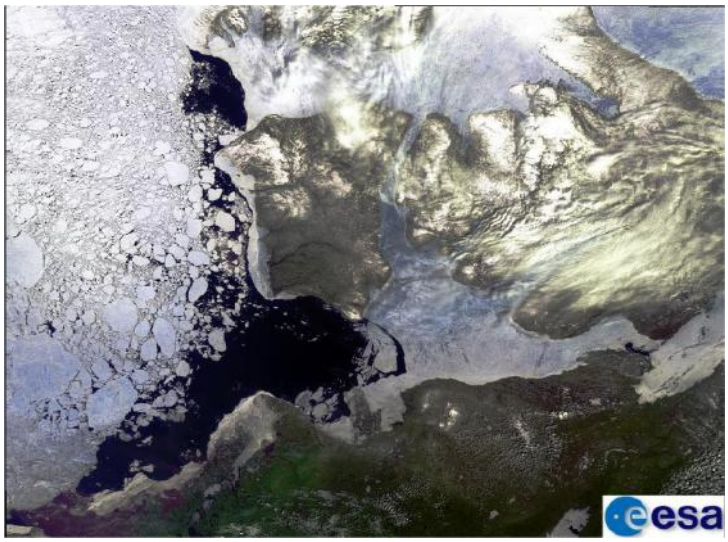
Met-ocean "POPS" Buoy
POPS buoy was not deployed during Leg 4 due to inadequate instrument capabilities. We are returning the profiler fish to met-ocean for a firmware update.

AVOS (Environment Canada MetObs System)
This instrument is not specifically our responsibility; however, we duly report that the instrument froze up on December 12th, was fixed immediately, but the Iridium service remained malfunctional. Matthew and the ship's electronic's officer (Rejean) were able to correct this on December 18th and the system is now functional.

Recommendations
In general, the data collection is proceeding as planned with no major issues that have not been resolved. As time progresses and we enter the winter it is imperative that all exposed instruments must be free of frost buildup and must be maintained at correct operating temperatures.

2.2.2. Optical Observation

Participants: Jinping Zhao and Tao Li



Key Lab for Polar Oceanography and Global Ocean Change

Ocean University of China

2007-12-20

Introduction: Light in dark Arctic Ocean

Solar radiation is the main heat source to the ocean. In ice covered ocean, part of solar energy can penetrate the sea ice to heating water. Light attenuation through sea ice is a main topic of Arctic study. Usually, optical observations are conducted in summer, as there is sun then.

However, the sunlight is declining projected onto the ice surface with the maximum solar height about 30 degree in summer. The sunlight in ice is dispersive and light paths sunlight traveled are more than ice thickness. So the attenuation measured with certain ice thickness is related to the solar height. The attenuation coefficient measured and referred to diffuse attenuation coefficient should be corrected by different solar height. People need to know the attenuation when the light is vertically projected on the ice, as then the light path is equal to the ice thickness. Unluckily, there is no such an opportunity from natural light in the Arctic Ocean.

As a great opportunity, a group from Ocean University of China participate the Leg-4 cruise to conduct an in situ optical experiment using an artificial lamp. The lamp is composed of 10 fluorescent lamps with the similar light spectrum of sun. By putting the lamp on the ice surface and shining downward, an underwater instrument, PRR-800 with 18 channels, records the intensity of the light, which is attenuated by sea ice and snow. The experiment tests both cases with snow and without snow in different ice thicknesses and different locations. The power of the lamp is about 500 W/m^2, little bit brighter than sunlight in summer. In the dark Arctic Ocean, the light must be a marvelous spectacle to the oceanic inhabitant.

It is expected that the experiment result can give the attenuation coefficient with the light path equal to ice thickness, which shows the nature of sea ice attenuation for different wavelength lights. Using this result, we can better estimate the light penetrating through sea ice with different solar heights and different ice thicknesses, which will be benefit to calculate the thermal budget through ice sheet in any season. Detected light under ice can illustrate the attenuation not only by ice thickness, but also by the particles and brine in the ice. The data can be used by ice physics and physical oceanography, and have potential connection with sea ice ecology.

Marched to the ice, the equipments are more than 100 kg, including a lamp, an ice auger, a power generator, two optical instruments, a computer, and a series of cables and connectors. During Leg-4, they have obtained successfully 36 measurements for attenuation measurements and 3 measurements for attenuation of lateral scattering light.

Instruments

Artificial lamp

We tried to make a xenon lamp, but failed to use it as it is too heavy to carry, about 120 kg. Also, the pot of the light is too small, about 30 by 30 cm.

We made a lamp in this cruise using fluorescent lamps. Each fluorescent lamp is 60 W, special for outdoor use. Ten fluorescent lamps are used to be composed of an integrated lamp. The lamps are parallelly aligned every 10 cm. The effective bright space of the lamp is 96 by 120 cm. The intensity of the lamp is about 500 W/m^2, little bit brighter than sunlight in summer this area. All the inner materials are decorated with white color to reflect light. The rectifiers of the fluorescent lamps are mounted on the back of the lamp.

Fig 2.1 Artificial lamp for the experiment

On sea ice, the lamp is powered by an electricity power generator, whose power is 1 kW to supply the system.

Fluorescent lamp as a light source is not very stable, because the fluorescent material will change with time. The other issues can also impact on the light stability. For example, output power from the power generator, the outside air temperature, the oscillation of wind speed, etc. Therefore, we need to test the stability of the lamp in various conditions to find the available period for measuring. The test results will guide the correct usage during the observation.

We used PRR-810 to measure the variation of light intensity in an indoor laboratory in Nov. 14, 2007. The instrument was putted 50 cm from the center of the lamp. The variation of light intensity is as shown in following figure. The horizontal coordinate is the number of record, 5 records per second.

After turn on the light, the intensity increased continuously in first 2.5 minutes. Since then the light intensity went down slowly. It cannot reach its stable in 15 minutes. During 15 minutes period, the intensity changed 10% of it.

After 15 minutes, the lamp became very stable. The change of light intensity was less than 1%. The error caused by the instable is acceptable. However, we still decide to calibrate the lamp in situ, in case the unexpected change in intensity of the lamp because of the weather and power.

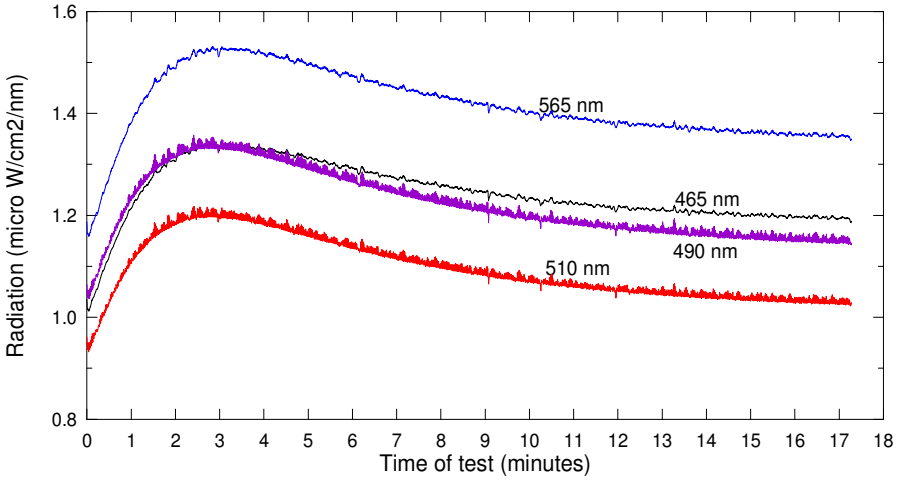


Fig. 2.2 Variation of light intensity with time

Though the spectrum of the lamp covers the solar spectra in violet, visible and infrared, the intensity of the lamp in each wavelength is different with that of solar radiation, because of the feature of the lamp, as shown in Fig 2.3. However, as the purpose of this experiment is to measure the attenuation rates, not the absolute values, the lamp is still satisfied to the purpose

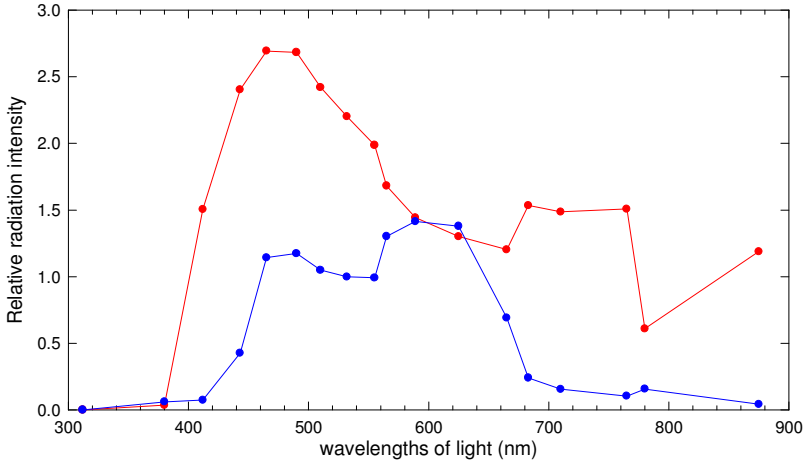

Fig 2.3 spectral distribution of intensity for both sunlight (red) and lamp (blue)

Optical Instruments

The instruments used for optical observation are high resolution Profiling Reflectance and Radiometer (PRR) made by Biospherical Instruments Inc. (BSI, USA). The system includes both an underwater profiler PRR-800 and a surface unit PRR-810, which collect signals simultaneously. Both instruments are all multispectral ones with very high resolution and sensitivity, enough to detect the light in dark condition under sea ice. The parameters for the system are as follows.

PRR-800
Optical features:
Wavelenths:313, 380, 412, 443, 490, 510, 520, 532, 555, 565, 589, 625, 665, 683, 710, 765, 780 and 875nm
Bandwidth: 10nm FWHM
Sensors:
Upwelling radiance, downwelling irradiance, dual axis inclinometer, detector array temperature, PRT water temperature, and pressure /depth
Irradiance array
Typical Saturation: 10^{5} $\mu Wcm^{-2}nm^{-1}$
Noise Equivalent Irradiance: $10^{-5}\mu Wcm^{-2}nm^{-1}$
Radiance array
Typical Saturation: 10^{-3} $Wcm^{-2}nm^{-1}$ sr^{-1}
Noise Equivalent Irradiance: 10^{-12} $Wcm^{-2}nm^{-1}$ sr^{-1}

Fig 2.4 A photo for PRR-800

PRR-810
Optical features:
Wavelenths: 313, 380, 412, 443, 490, 510, 520, 532, 555, 565, 589, 625, 665, 683, 710, 765, 780 and 875nm
Bandwidth: 10nm FWHM
Sensors:
Downwelling irradiance and detector array temperature

PRR-800/810 is a cable linked system to collect data directly by a computer during the deployment. A deck unit links PRR-800, PRR-810 and computer tocontrol the data acquirement.

The wavelengths of the instruments are carefully chosen for multiple scientific purposes.

Ultraviolet: 313 and 380.
Visible: 412, 443, 490, 510, 520, 532, 555, 565, 589, 625, 665, 683, and 710
Infrared: 765,780 and 875nm

These wavelengths cover the most high energy part of solar spectrum, as shown in Fig. 2.6. By this instrument, the spectral distribution of attenuation can be obtained.

The sampling frequency of PRR800/810 is 5Hz, a record per 0.2 second.

Fig 2.5 A photo for PRR-810

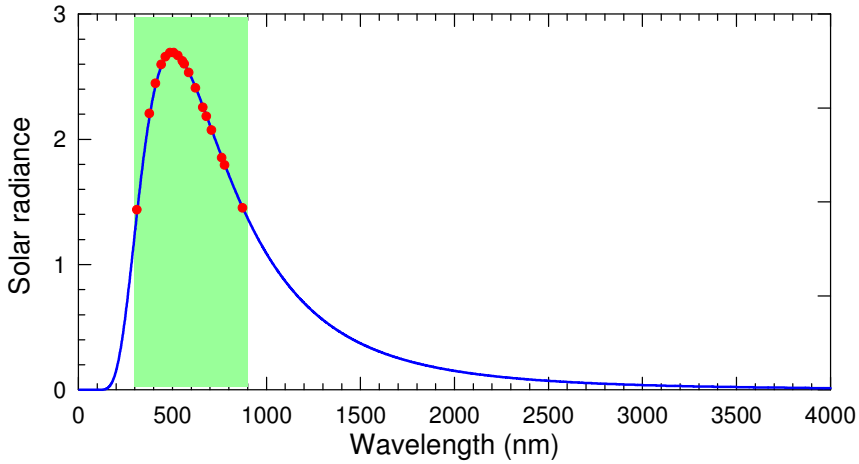

Fig 2.6 Wavelengths of PRR-800/810 in solar radiation spectra
Unit of vertical coordinate is 10^7 W m^{-2} Sr^{-1} μm^{-1}. Red dots express the wavelengths of the instruments. Green shade shows the range of 300-900nmwavelength, whose energy is about 0.628 of total solar radiation.

Deployment for vertical attenuation experiment
Through a hole with diameter of 20 cm, the underwater instrument, PRR-800, is deployed with a cable. Then, rotating the connector, the instrument is turned 90 degree to the bottom of ice.

The lamp is put on the surface of the snow. The consistency of this manner with that of hanging the lamp is demonstrated.

A calibration measurement is conducted by PRR-810 just after the underwater measurements to ensure measuring correct intensity.

The data collection unit and computer were put on a box to real-time monitor the tilt of the underwater instruments and the data quality.

The measurement is for two cases, snow covered and snow removed.

Deployment for lateral attenuation experiment
Lateral attenuation experiment is for measuring the attenuation feature of the lateral scattering light. Lateral scattering is impossible to measure in natural light. The lateral attenuation coefficient includes much information to the structure of sea ice.

Firstly we need to create a basin by auger with the width of 10 cm and length of 50 cm for putting PRR-810 inside horizontally. The depth of the basin depends on the thickness of sea ice, the deeper, and the better. Observation is in different level vertically to measure the change.

The measurement adopts the manner that the instrument is in fixed position, but the light lamp is in moving. The lamp moves from the position just above the instrument to away from the instrument. In total, 1.70 m is enough to leave the domain with scattering light.

The moving of the lamp will be stopped every 5 cm to keep the reliable record of the radiation value.

The data collection unit and computer were put on a box to real-time monitor data quality. The underwater unit is not used in this measurement, but has to be linked to the system.

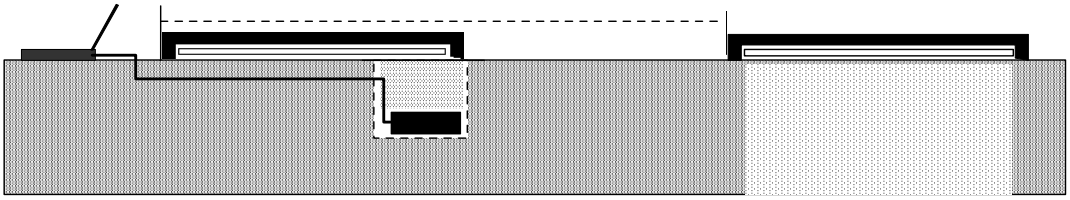

Fig. 3.2 measurement for lateral scatting light

Deployment for CTD

In each station, we conducted a CTD profile down to 50 meters to understand the water condition just below sea ice.

Guide to the experiment for optical attenuation of sea ice and snow

Equipments to the field

Following equipments are needed to carry on the field

No.	Name of equipment	Weight	Carrier
1	Fluorescent lamp	20 kg	1+2
2	Optical instruments	15 kg	1
3	Cables + 250W lamp	15 kg	1
4	Power generator	10 kg	1
5	Jeffy driller	5 kg	2
6	Underwater frame	15 kg	2
7	Computer	2 kg	2
8	Desk box of optical instruments	4 kg	1
9	Tripod, ruler, toolbox, spade	3 kg	2

Pre-experiment for the lamp

A detailed pre-experiment is for measuring the light field of the lamp to be used in calculating the attenuation by snow and ice.

Step	Experiment
1	Put the lamp with the normal parallel to the ground
2	Measure light intensity distribution in each rectangular section at 0.2, 0.4, 0.6, 0.8, 1.0, 1.2, 1.5, 2.0, 2.5, 3.0, 3.5, 4.0 meters
3	Calculate the scatting rate of the lamp with distance

Operational program for nature light

For nature light, we need to measure the downwelling radiation to the ice, upwelling reflection from ice, and downwelling radiation to the bottom of ice.

Step	Operation	Note
1	Choose proper experiment field	Avoid to step on the field
2	Start ice driller and drill a hole on ice	Measure ice thickness
3	Generate electricity	Use a connector with 3 plugs
4	Link and deploy PRR-800	Put on accurate position
5	Put PRR-810 on tripod	
6	Start instruments system	Keep computer warm before using
7	Measure with snow	
8	Remove snow and measure	Measure snow thickness
9	Finish	

Operational program for artificial light
For artificial light, we do not need to measure the incidence and reflection.

Step	Operation	Note
1	Choose proper experiment field	Avoid to step on the field
2	Start ice driller and drill a hole on ice	Measure ice thickness
3	Generate electricity	Use a connector with 3 plugs
4	Switch on the lamp	Preheating bout 15 minutes
5	Link and deploy PRR-800	Put on accurate position
6	Put PRR-810 on tripod	
7	Start instruments system	Keep computer warm before using
8	Measure downwellings with snow	
9	calibration with snow	
10	Remove snow and measure	Measure snow thickness
11	calibration without snow	
12	Finish	

Data report during Leg-4

During Leg-4, we worked on two kinds of measurements, light attenuation through sea ice and lateral light attenuation.

Light attenuation through sea ice
During Leg-4, about 36 measurements are conducted in 15 stations. The following list (Table 5.1) is the simple description for these measurements.

Table 5.1 Information for vertical attenuation measurements

№	Stn	Ice	Snow	Latitude	Longitude	File name
1	1117			69°51.9560'N	126°29.3079 'W	2007_11_15_2147.mdb , 2007_11_15_2235.mdb
2	1117	37cm	2cm	69°51.9560'N	126°29.3079 'W	2007_11_15_0012.mdb

Attenuation for lateral scattering light

The measurement for lateral scattering light attenuation is an experiment. During Leg-4, we worked on two stations with fourteen measurements. The all measurements are listed in Table 5.2.

Table 5.2 Information for lateral attenuation measurements

No	Stn	Date	Level	Lamp width	File name

CTD measurements

Twelve CTD profiles are measured in total. The data has been corrected by its software. The information for these data is as follows (Table 5.3).

Table 5.3 Station information for CTD

No.	No. PRR	Stn.	Deploy Dep.	Latitude	Longitude	File name

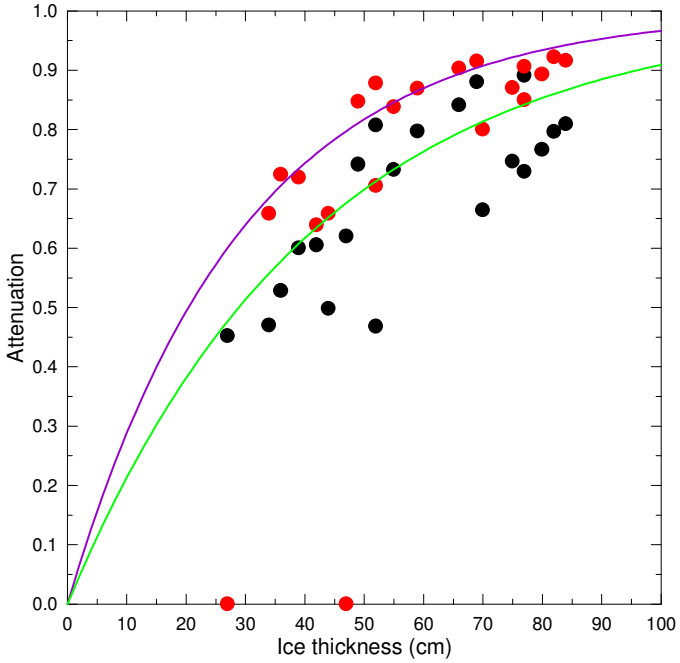
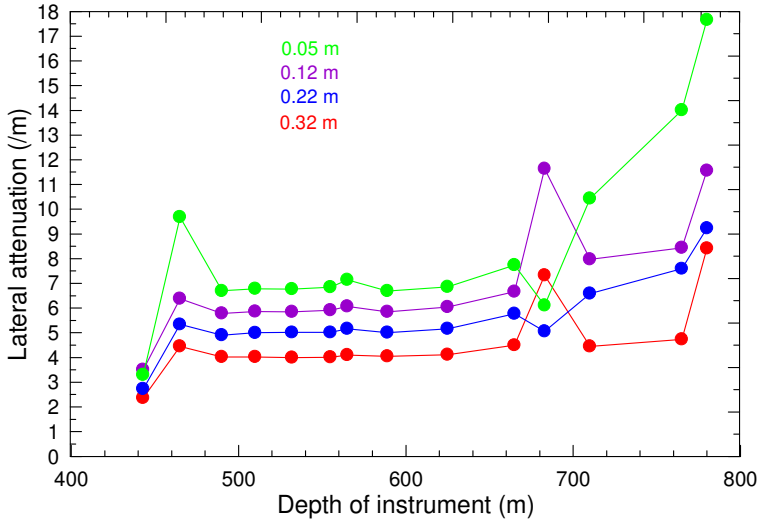
Research initiatives



Transmissions measured in different locations and with different ice thickness

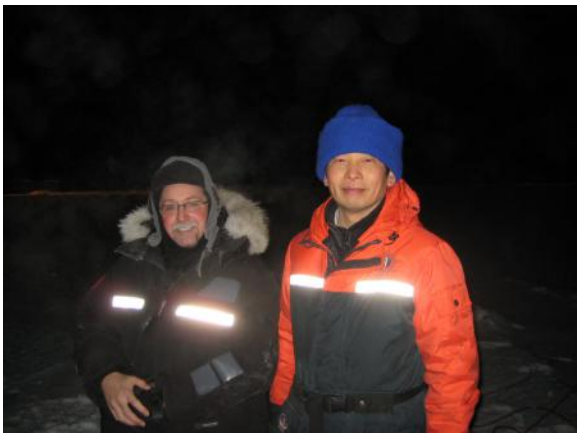


Spectral attenuation coefficient of lateral scattering light in different levels

We greatly appreciate the chief scientists of CFL, Dr. **David Barber**, to provide us the opportunity to participate the cruise. During the cruise, he gave us much help and suggestions to our work, and he created lots of opportunities and convenience to us for in situ measurements. We also appreciate **Gary Stern**, the cruise chief scientist, who supported us as much as possible for our field observation and scientific research.
We greatly appreciate the Captain of Amundsen, **Jolien Stephane**, and his crew to provide in the maximum extent help to us. Specially, we appreciate crew members, **Rock Poulin**, **Steeve Quirion**, **Daniel Cloutier**, ect, who always provide necessary help to us in need during the cruise.
Before and during this cruise, **Phil Hwang** provides us many helps in preparing equipments, instruments, cloths and materials for field work. His help is the key to our successful observation. We got lots help from **Sylvain Blondeau** in producing and improving our equipments. Here we hope to express our earnest appreciations to him.
We appreciate **Vernon Amos** and **Trevoe Lueas**, who are responsible to guard our safety in so many times down to the ice.
We appreciate the **China IPY Office**, who offers us support to participate the cruise. We also appreciate the **Nature Science Foundation of China** for their support in the key project with No. 40631006.

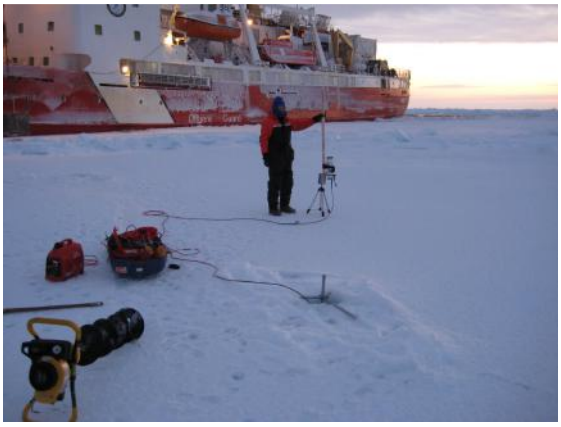
Appendix 1: Photos in working

With chief scientist David Barber



With chief scientist Gary Stern

We are coming

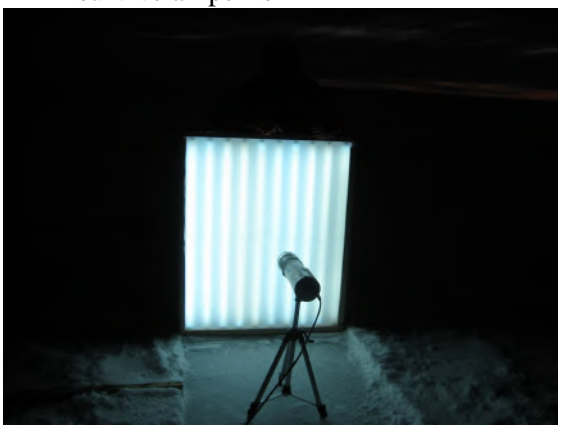


Measure the last sunlight

It is not too thick

survive all perils

A light in the dark



Take a photo for the light

Hidden in ice

Learn the ropes

Illuminate the world

Walking light

Our sun

Who can see me?

Description

Good weather, wind is weak, and temperature is not too low. Nearly now snow at all, but there is some snow pot on it. We observed two times for both with and without snow pot.

(1) Measure with snow pot
(2) Tried to calibrate, but the electricity broke down.
(3) Measure with snow pot again
(4) Calibrate
(5) Clean the snow pot
(6) Measure without snow pot
(7) Move across 10 cm to test the change of light intensity.
(8) Calibrate again

Description

Ice is rough. Besides ship there is a ridge. Across the ridge, ice smoother, but still very rough. It is impossible to find a ice flat enough. Where we observed is a relative flat and small area. As there are some small ice blocks frozen on ice sheet, the lamp cannot cover the ice without gap. Anyway, the last arrange for the lamp is good.

(1) Lamp is lightened during the preparation.
(2) Measure with now.
(3) Calibration.
(4) We took too long time to calibrate, so we measured again, but the intensity changed much.
(5) Clean snow, but ice surface is still white.
(6) Measure without snow
(7) Calibration

It is windy. 35 knot/sec. Very cold.

2.3. Team 4

2.3.1. Zooplankton & Fish/ Acoustic

Participants: Hélen Cloutier (U.Laval), Louis Létourneau (U.Laval), Sylvain Blondeau, Maxime Dumais (electronician technician from U Laval)

General objective and field program

The general objective of our team is marine productivity and sustained exploitation of emerging fisheries which is to assess the impact of sea-ice cover reduction and increasing sea temperatures on biological productivity, fisheries resources and marine Mammal populations of the coastal Canadian arctic. Aboard the CCGS Amundsen, we collect indices of the ecosystem maturity late in autumn and at the beginning of the winter (November and December).

However, the 2007 cruise differed from the previous missions, being a component of the Canada's contribution to the International Polar Year, the ship CCGS Amundsen left Québec in August for a mission of 15 months. Since October 18th date we were begin-Ning the Circumpolar Flaw Lead Study (CFL) which will examine on an annual cycle how the physical processes moderate biogeochemical processes within the changing northern flaw lead ecosystem nearby Banks Island (Beaufort Sea). Therefore, the sampling during this period can be seen as a pre-winter survey of the flaw lead area to get an indication of the status of the marine ecosystem at the end of the growth season and associated physical forcing. Our multidisciplinary ArcticNet team is thus strongly linked with Team 4 (Pelagic and Benthic Foodwebs – Fortier) and Team 7 (Carbon Fluxes – Tremblay) of the CFL program

Operations during the ArcticNet-CFL leg 4 were spread on the East-West gradient of the Canadian Arctic. This represented a large spectrum of sampling conditions and three oceanographic regions were visited the south-eastern Beaufort Sea (Western Arctic) comprised of the Franklin Bay and Banks Shelves, and of the Amundsen Gulf area (the CFL study region).

The main field objectives of our multitask ArcticNet Theme 1.4 sub-team were:

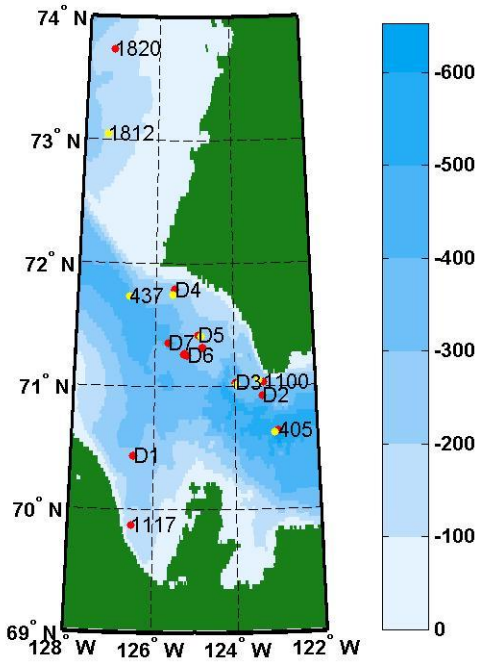
1) To assess zooplankton / fish abundance and diversity by using various plankton nets.

2) To track zooplankton / fish biomass and distribution with the EK60 Echosounder.

In addition, zooplankton samples collected during leg 4 are also used in other ArcticNet-CFL subprojects such as the cycling of contaminants (G. Stern). As well, part of the samples collected will be used in a study to identify the sources and pathways of omega-3 in the arctic marine food chain (J. Michaud, E. Dewaily and L. Fortier) and is linked to the ArcticNet theme 1.5 that is focussing on the importance of omega-3 fatty acid in the traditional diet of Inuit communities. Also as part of the CFL Team 4 on the pelagic food web, the assessment of the respiration rates of the zooplankton community by the Electron Transfer Sysem (ETS) activity method was performed at chosen stations (G. Darnis and L. Fortier). At some stations, zooplankton samples were also collected for genetic studies at UQAR (France Dufresne and Adriana Radulovici).

In total, 13 stations were visited for zooplankton. However, the ice conditions (multiyear ice floes or fast-growing sea ice) severely constrained the sampling at many stations during leg 4. Acoustics EK60 monitoring was done continuously during the whole cruise.). The Table 1 (p. 4) summarizes the sampling activities at each of the 12 stations. And the details of the operations are fully described in the following sections: 1- Zooplankton.

Figure 1: Leg 4 stations



Graphic by Marie-Emmanuelle Rail (INRS)

Vertical tows (1m^2- Net, Hydrobios)

1-m^2 Square (Frame rigged with 1 square m^2 opening nets (1 x 200, µm mesh), out-rigged with a 10 cm diameter net (50 µm) and equipped with flowmeter (1 TSKs). This net is used for integrated water column sampling. When deploying, winch speed down was <20 m/min to avoid mixing of the nets, and winch speed up was 40m/min. The content of one 200 µm (TSK-QT) and the 50 µm mesh-net were preserved in formaldehyde for taxonomy (Fortier). The content of the others casts nets were sorted for contaminants, lipids and genetics studies. At some stations, ETS assays were performed using one of the integrated tows (see Table 2 for details). This gear was systematically deployed at all full stations.(photo a)

Hydrobios: Multi plankton sampler (photo b) equipped with nine 200 µm-mesh nets (opening 0.5 m^2). This was allowing for depth specific sampling of the water column. The *Hydrobios* is also equipped with a CTD to record water column properties while collecting biological samples. When deploying, winch speeds down and up were both 40m/min. The *Hydrobios* was deployed at full stations in every region when conditions were favourable. At some stations, the content of each net was divided between preservations (4% buffered formaldehyde) and ETS assays were performed for. Please note that the recurrent problem with the *Hydrobios*'s flowmeters has not been resolved yet (they do not work in the water, while they work on deck).

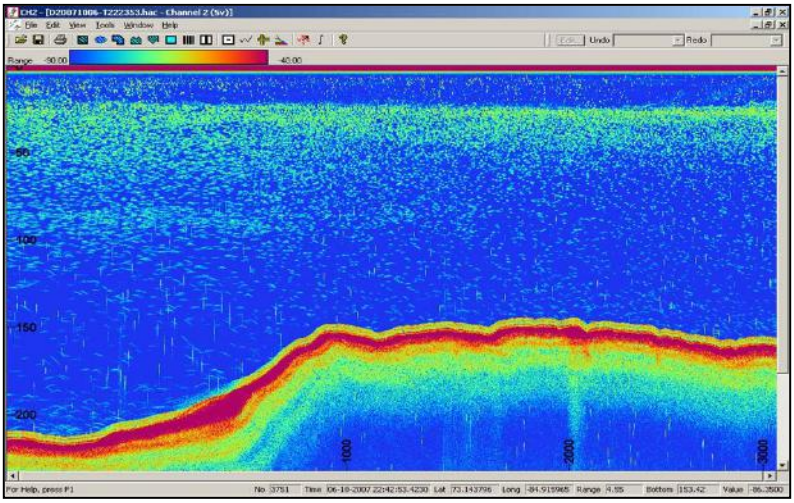
Acoustic monitoring

The Amundsen is equipped with a scientific echosounder, the EK-60, to continuously monitor the distribution of zooplankton and fish. A particular attention is devoted to Arctic cod, *Boreogadus saida*, which plays a key role in the Arctic marine ecosystem. During the first part of leg 3, an acoustic layer was detected between 20 and 100 m below the surface (Figure 3) everywhere along the route of the vessel from Resolute to the Greenland coast. Based on the analysis of the split-beam information, it seemed to contain mostly small fish and large zooplankton. When comparing the vertical distribution of the echoes to that of the water column characteristics obtained from Rosette casts, the acoustic layer appears to be associated with an intrusion of warmer waters below the surface. Another acoustic layer likely resulting from the presence of larger fish and associated with different water mass was present between 250 and 500 m. This layer, which according to its multifrequency acoustic signature also contains zooplankton, was more concentrated in the western part of Lancaster Sound. It settled on the bottom of the NOW polynya around the 350 m depth contour, especially on the Canadian side.

Figure 2: Typical EK-60 feature in Eastern Arctic



2.4. Team 6

PIs: Tim Papakyriakou (U of M), Lisa Miller (IOS), Jean-Louis Tison (U.L.B.)

2.4.1. Surface Meteorology and Flux Project

Brent Else

Introduction
The surface meteorology and flux program (CFL Team 6) is designed to record basic meteorological conditions and to study exchanges of momentum, heat and mass across the atmosphere-sea ice-ocean interface. The main value of this program to the overarching objectives of Team 6 is the direct measurement of CO_2 fluxes.

Fluxes of CO_2 are measured by the eddy covariance technique, which is dependent only on atmospheric measurements. Although measurement of these fluxes is extremely useful information, it is essentially meaningless without an understanding of the processes (physical, biological and chemical) that drive gas exchange. In an open-ocean situation this context is largely provided by measurement of sea-surface pCO_2, but the situation becomes much more complex when a sea ice cover is included in the equation.

This section of the CFL Team 6 cruise report reviews the atmospheric and sea surface pCO_2 measurements that were made during Leg 6. Other sections of the report will deal with the sea ice measurements that were made in support of the CO_2 flux measurements.

Micrometeorology and Eddy Covariance Flux Tower

Methods
The micrometeorological tower located on the front deck of the Amundsen (Figure 1.1) provided continuous monitoring of meteorological variables and eddy covariance parameters. The tower consists of slow response sensors that record bulk meteorological conditions (air temperature, humidity, wind speed/direction, surface temperature) and fast response sensors that record the eddy covariance parameters (CO_2/H_2O concentration, 3D wind velocity, 3D ship motion, air temperature) (Table 1.1). In addition, radiation sensors (Figure 1.1, Table 1.1) were installed on the roof of the wheelhouse to provide information on incoming longwave, shortwave and photosynethetically active radiation. All data was logged to Campbell Scientific dataloggers; a model CR5000 logger was used for the eddy covariance data, a CR1000 logger for the slow response met data, and a CR23X for the radiation data. All loggers were synchronized to UTC time using the ship's GPS system as a reference.

The eddy covariance system on the tower makes use of two separate gas analyzers and a single 3D sonic anemometer. The dual gas analyzers system allows us to make use of both closed path and open path eddy covariance systems. The open path gas analyzer has the benefit of making measurements concurrently with the sonic anemometer, but the closed path gas analyzer is not as easily disturbed by adverse weather conditions.

In order to make sure that the two systems are comparable, careful calibrations were performed on both instruments. The closed path system is based on a LI-7000 gas analyzer which employs two optical cells, one of which was used to monitor the drift of the instrument by constantly passing a stream of ultra-high purity N_2. In addition, the sample cell of the instrument was calibrated daily using the ultra-high purity N_2 to zero the CO_2 and H_2O measurements, and a reference gas of known CO_2 to span the instrument. Occasionally, a span calibration of the H_2O sensor was performed using

a dew point generator (model LI-610). The open path gas analyzer (LI-7500) could not be calibrated as conveniently, and so it was calibrated approximately every three weeks. In general, we find that this is effective for this particular instrument, which does not drift significantly over time.

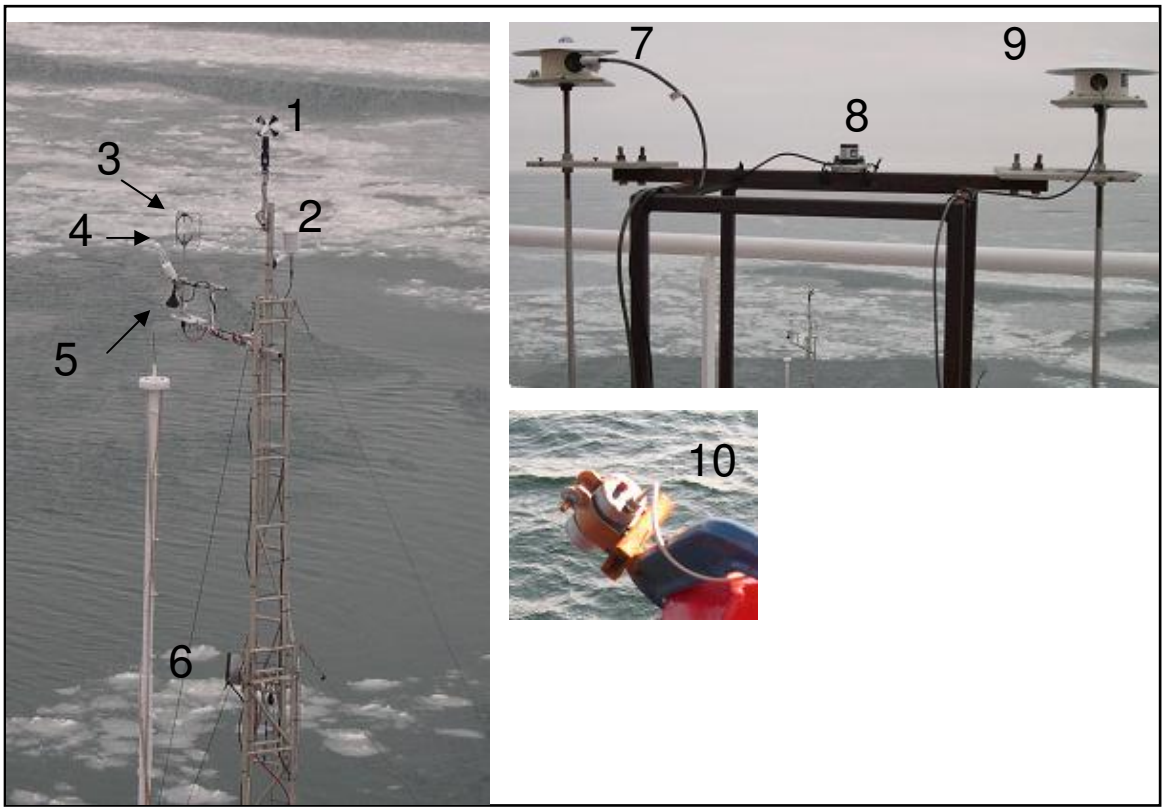

Figure 1.1: Meteorology and flux program instrument setup. See Table 1 for description of instruments based on the numbers. Note that on Nov. 18 the Motion Pak (6) was moved to the rear face of the tower to facilitate easier motion correction.

Table 1.1: Description of instruments shown in Fig. 1.1.

Sample data

As an example of the slow response meteorological data, Figure 1.2 shows the evolution of air temperature and wind speed over one day at Station D7 (a first year sea ice floe, ~70cm depth). An example of the rapid response flux data is shown in Figure 1.3, which shows 10 minutes of vertical wind speed and CO_2 concentration. A great deal of processing will be required to calculate actual fluxes of CO_2, and to filter out erroneous data.

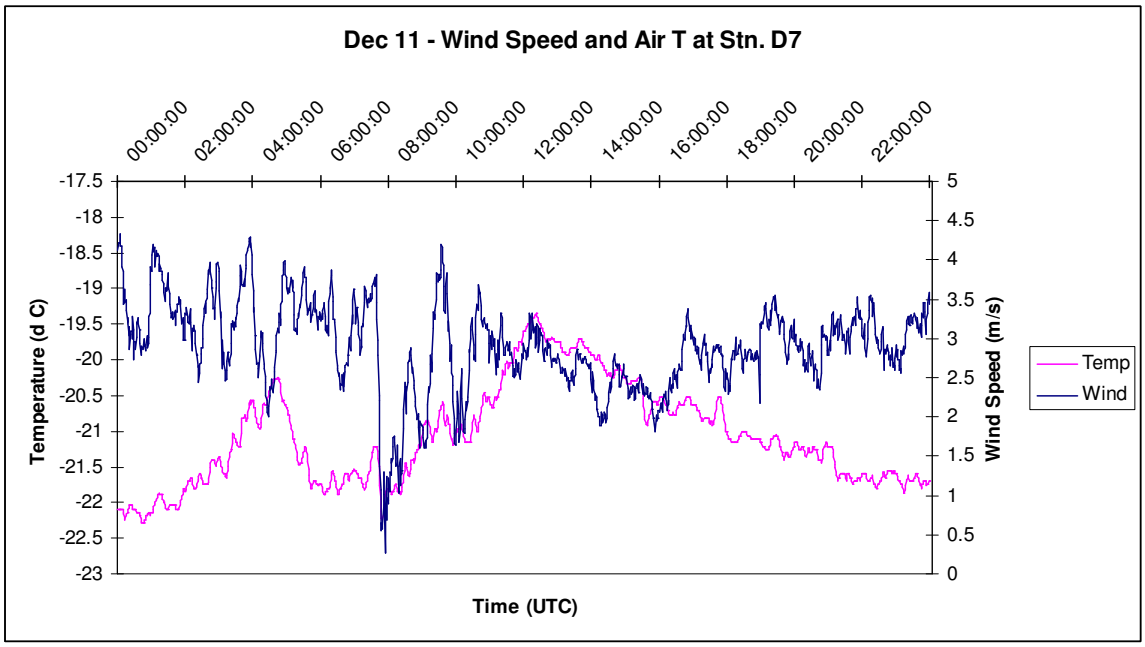

Figure 1.2: Slow response meteorological data example; wind speed and air temperature (24 hrs)..

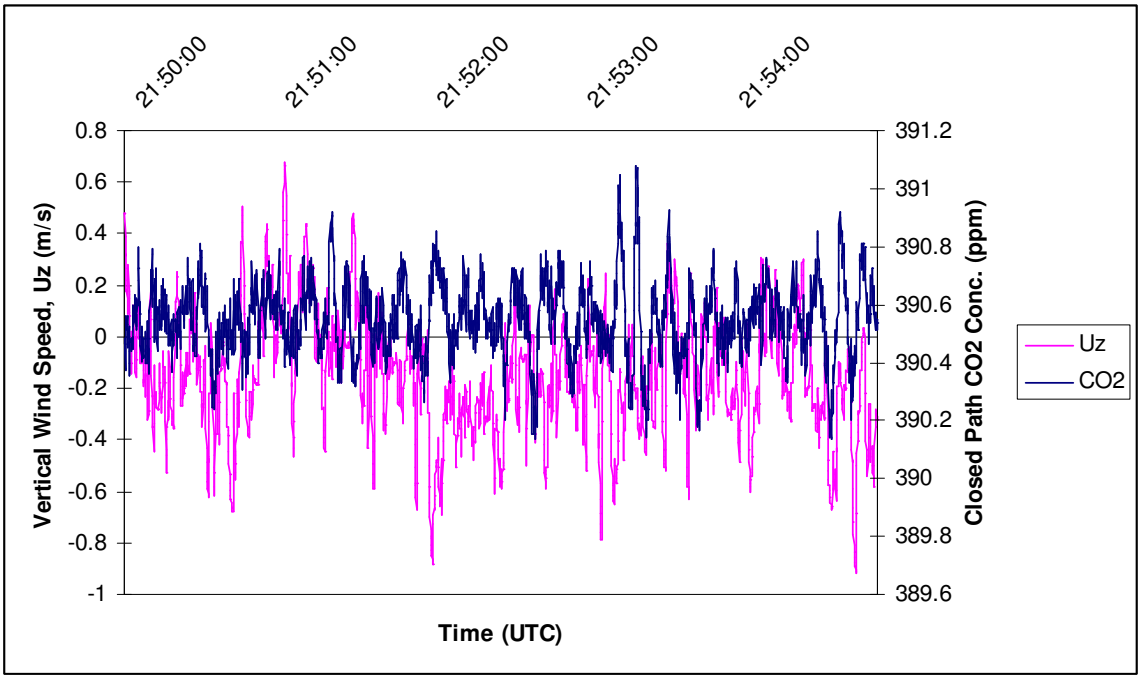

Figure 1.3: Fast response flux data example; vertical wind speed and closed path $_{CO2}$ concentration (10 min).

Notes

The meteorological tower ran consistently for the duration of the leg (Nov. 8-Dec. 20) with the exception of a brief period when the tower was taken down for maintenance (Nov 18). However, for significant periods of time during the leg certain sensors were inoperable due to atmospheric conditions. The most common problem encountered during this leg was riming due to the cold, moist conditions. This problem most seriously affected the LI-7500, which was very difficult to keep clean. The problem also affected the sonic anemometer, but to a much lesser degree. The extent of data lost due to atmospheric conditions cannot be estimated at this time, and will only be known once post processing is complete.

A second key note for this leg is that a problem with the calibration routine for the LI-7000 gas analyzer was identified. Due to the high flow rate required for the closed path sample line, the sample cell of the LI-7000 operates at a low pressure (~50 kPa). On previous legs the LI-7000 was calibrated at a pressure of ~100 kPa, which apparently caused a systematically high reading of CO_2 concentration. This problem was rectified on Dec. 6 by making some minor adjustments to the piping systems. All data collected prior to Dec. 6 will need to be corrected for this error.

Finally, a minor change was made to the tower on Nov. 18 by changing the motion sensor to the back face of the tower. This change will allow for easier motion correction, because it aligns the axes of the sensor with the sonic anemometer. All data prior to this date will have to take into consideration the offset of the motion pak relative to the axes of the anemometer.

On-track pCO_2 System

Methods

A custom-built pCO_2 system was utilized on this leg to measure dissolved $_{CO2}$ at the sea surface in near real time. The system (Figure 1.4) is located in the engine room of the Amundsen, and draws sample water from the ship's clean water intake. The water is passed into a sealed container through a shower head, maintaining a constant headspace. This set up allows the air in the headspace to come into equilibrium with the CO_2 concentration of the seawater, and the air is then cycled from the container into the LI-7000 gas analyzer in a closed loop. Thermocouples are used to measure water temperature immediately before entering the equilibration chamber, and to measure the temperature of the air in the chamber. All data is logged to a Campbell Scientific CR1000 datalogger.

The LI-7000 gas analyzer was calibrated daily using ultra-high purity N_2 as a zero gas, and a gas with known CO_2 concentration as a span gas. Spanning of the H_2O sensor was not necessary because a desiccant column removes H_2O from the air stream before passing into the sample cell. As with the closed path system, a stream of N_2 is constantly cycled through the reference cell of the LI-7000 to monitor and correct for drift of the instrument.

Figure 1.4: The on-track pCO_2 system located in the engine room of the Amundsen. The equilibration chamber is the clear cylinder (left bottom) and the gas analyzer is the box with the digital display.

Sample Data
Figure 5 shows an example of a single day of CO_2 data recorded by the on-track system, along with water temperature. Further processing must still be undertaken to correct the values for changes in temperature that occur due to the length of the sample line, and to properly calculate pCO_2.

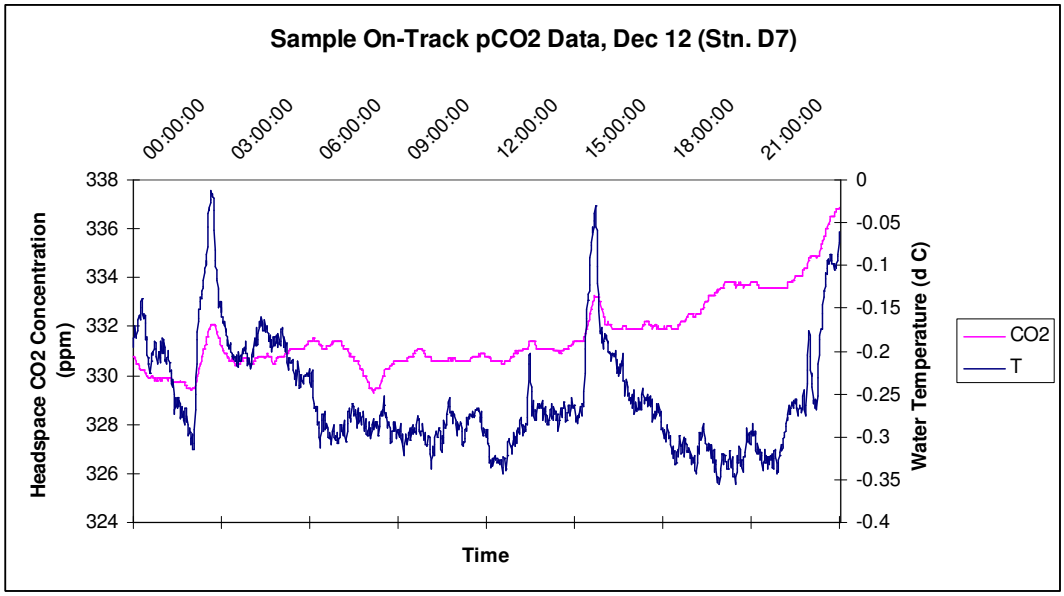

Figure 1.5: Sample on-track pCO_2 data (CO_2 and water temperature)

Notes
The on-track pCO_2 system was active for the duration of the leg, with some minor interruptions for maintenance. Major interruptions in data collection were experienced when the ship was breaking ice, which either reduced the flow of water into the equilibration tank, or completely blocked it. In the case of blocked flow, the data is lost, but tests will have to be conducted to determine if data obtained with low water flow is useful. No changes were made to the system during this leg.

2.4.2. CO_2 in Sea Ice Project

Brent Else

Introduction
The primary focus of Team 6 is to gain a better understanding of the cycling of climatologically important gases in Arctic seas. A large base of knowledge already exists regarding air-sea gas exchange, but considerably less is known about the exchange of gases in an ice covered ocean. During CFL Leg 4, a sampling program was carried out to examine CO_2 in sea ice with the goal of creating a context against which measurements made by the eddy covariance flux system (section 1) can be interpreted.

To gather this contextual information, several different methods were used to understand the distribution of CO_2 in sea ice. Silicon "peepers" were deployed to measure profiles of CO_2 within the ice matrix and "sackholes" were drilled to collect brines for analysis of dissolved CO_2 content. To determine fluxes of CO2 directly associated with the sea ice, a flux chamber was used. This sampling provides a very unique dataset that will allow us to understand the state of sea ice with respect to CO2 early in the ice growth season.

Peepers

Methods

Silicon chambers (approximately 15cm in length, 5cm in diameter) were deployed in the ice, either in sackholes or in auger holes drilled completely through the ice (Figure 2.1). The silicone membrane is permeable to gas exchange, and if the peeper is left in the ice for a long period of time (at least 24hrs) the ambient gas in the peeper should come into equilibrium with gas that exists in brines and air pockets in the sea ice. Stainless steel tubing was used to sample the gas in the peepers with a gas analyzer (Licor model LI-820). The setup was designed to cycle air from the peepers through the gas analyzer in a closed loop. Data from the LI-820 was logged to a Campbell Scientific CR10X data logger at a frequency of 1 Hz. This allowed for the observation of a peak in CO_2 concentration as the gas in the peeper cycles through the gas analyzer. Although this eventually results in mixing of ambient atmosphere into the peeper chamber, we believe that the initial peak is representative of the CO_2 concentration in the ice.

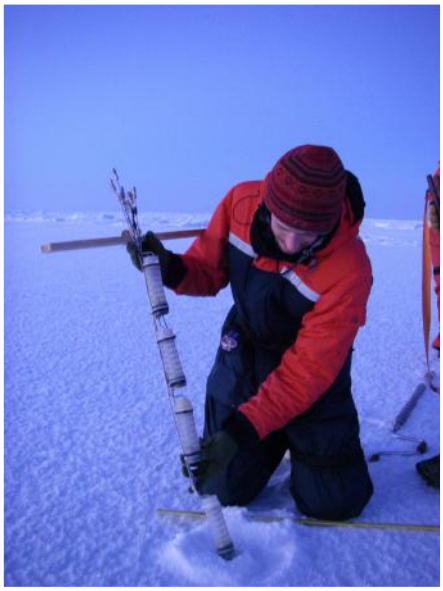

Figure 2.1: Deployment of a peeper array into an auger hole drilled through the ice to the ocean.

Deployment dates/locations

Table 2.1: Deployment date/location for peeper sampling. All times/dates UTC.

Site	Deployment Date	Removal Date	Sample Dates/Time	Notes
D5	Dec. 6, 0000	Dec. 8, 1700	Dec. 7, 0000 Dec. 8, 0000 Dec. 8, 1630	-Deployed 5 peepers; 3 in 20 cm sackholes, 2 in a 40cm sackhole array (1 at 20cm, 1 at 40cm)
D7	Dec. 11, 1800 (array) Dec. 12, 1800 (sackholes) Dec. 13, 1800 (50cm sackhole)	Dec. 17, 1730	Dec. 13, 0300 (array only) Dec. 14, 0400 (except 50cm sackhole) Dec. 15, 0000 Dec. 16, 0300 Dec. 17, 0300	-Deployed an array of peepers through an auger hole to the ocean (Fig. 1); depths of 20cm, 40cm, 60cm and 85 cm (i.e. in the water below the interface) -Deployed 4 peepers in 20cm sackholes, 1 in a 40cm sackhole, 1 in 50cm sackhole.

Sample data

Figure 2.2 shows the sample output from the LI-820 gas analyzer for one peeper run. A clear peak is observed at 725 ppm, which is indicative of the CO_2 concentration in the ice. Figure 2.3 shows the observations of the peeper array deployed at station D7 during one sampling period, showing significant vertical variation.

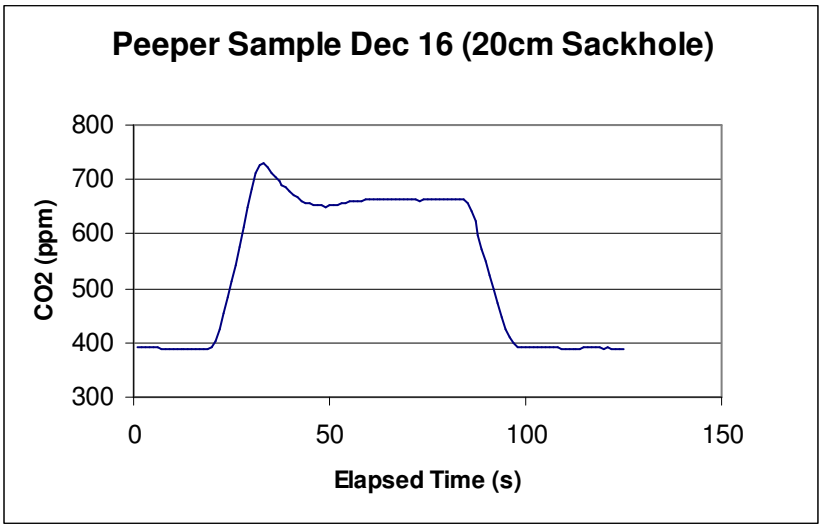

Figure 2.2: Raw peeper sampling data from a 20cm peeper at Stn. D7

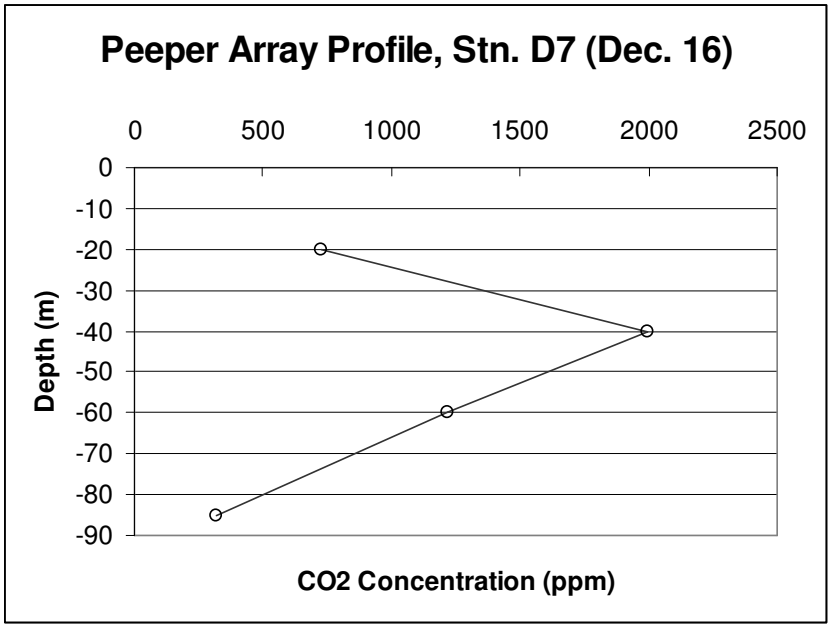

Figure 2.3: Sample profile from the peeper array shown in Fig. 1.

Peeper notes

In some peepers at station D7 the CO_2 concentration exceeded the limit of the gas analyzer (2000 ppm). However, it seems likely that the peak can be estimated by graphing the data (e.g. Fig. 2). In the future, the LI-820 should be set to a larger range by modifying the optical bench of the analyzer cell. During this leg we lacked the materials to make this modification.

Brine Sampling

Methods

In order to sample dissolved CO_2 in brine, sackholes were drilled by coring down to a desired depth without breaking through to the ocean interface. These holes were capped with an insulating barrier to prevent gas exchange, and left at least 6 hours to accumulate brine. Initially, we attempted to sample the brines in situ, using a portable pCO_2 system. Unfortunately, we had problems with the sample lines freezing, and as a solution we were forced to collect the brine in glass jars. The sampling was done with a syringe and surgical tubing, being careful to avoid injection of bubbles. The jars were sealed with greased glass stoppers to prevent gas exchange. The jars were returned to the ship where they were sampled immediately using the portable pCO_2 system (Figure 2.4).

The portable pCO_2 system cycles water through a membrane contractor (LiquiCel ® minimodule) and subsequently passes the equilibrated gas through a LI-820 gas analyzer in a closed loop. In order to allow the system time to equilibrate, the water was cycled through the glass jar, and left to run for at least 30 minutes. Although this certainly allows some gas exchange, it is a desirable method because the amount of gas exchange can be quantified to a certain degree. The pCO_2 system also measures water temperature as it passes through the equilibrator, but as a check on this system a temperature probe was inserted into the bottle and temperature in the bottle was measured at regular intervals. These temperature measurements will be important when analyzing the data, since perturbations in temperature from the in situ state likely have an effect on the carbonate equilibrium.

Figure 2.4: Sampling set up for brine pCO_2. In later instances the bottle was kept at a lower temperature by working in an ice bath, or a cool room. The bottle top was capped with parafilm to limit gas exchange.

Sample Dates/Locations

Table 2.2: Deployment date/location for brine sampling. All times/dates UTC.

Station	Sample Date	Notes
D4	Dec. 7	-2 samples at 20cm
D4	Dec. 8	-2 samples at 20cm
D7	Dec. 13	-1 sample at 20cm, 1 sample at 40cm
D7	Dec. 16	-1 sample at 20cm, 1 sample at 40cm

Sample Data
Figure 2.5 shows raw data from one pCO_2 brine sample. There is a clear period of time when CO_2 is increasing as the gas stream equilibrates with the water sample. After this, the sample appears to degass. From this information, we can probably make a reasonable estimate of dissolved CO_2 in brine.

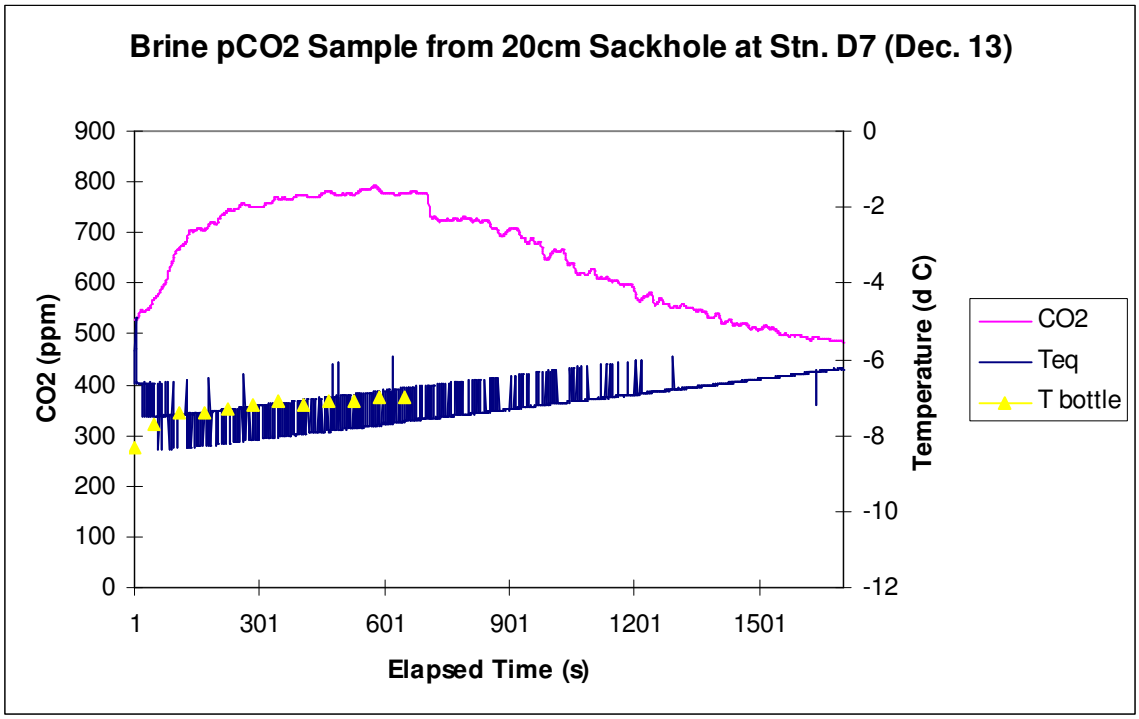

Figure 2.5: Raw data from one brine sampling experiment. Teq is the water temperature recorded by the pCO_2 system, and T bottle is the temperature manually recorded using the temperature probe.

Notes
It is unclear at this time exactly how to interpret the data obtained using this collection method (see Figure 2.5). In situ sampling would generally be more desireable, however the method of cycling the brine through the gas analyzer and back into a sackhole would likely be just as problematic with respect to changes in temperature and gas exchange. In fact, the volume of water collected in a single shallow brine hole can be considerably less than the jars, in which case gas exchange could be an even bigger problem. Further refinements of this method are probably necessary in future legs to ensure reliable data is collected.

Flux Chamber

Methods
When measuring fluxes of CO_2 with the eddy covariance system, there is always some ambiguity regarding the "footprint" of the measurement. This is a problem when dealing with a highly spatially variable icescape such as the one encountered in Leg 4. To resolve some of this ambiguity, a flux chamber was deployed over certain ice types to directly measure the flux of CO_2.

The flux chamber is a sealed cylinder connected the LI-820 gas analyzer used in the peeper and brine experiments (Figure 2.6). Gas is continually cycled through the chamber and the analyzer in a closed loop, and measurements are recorded every 20 seconds on the CR10X datalogger. A small fan in the top of the flux chamber homogenizes the air to ensure that a gradient of CO_2 does not build up in the chamber. The theory of operation is quite simple – if the concentration of CO_2 in the chamber changes, a flux of CO_2 must be occurring related to the sea ice.

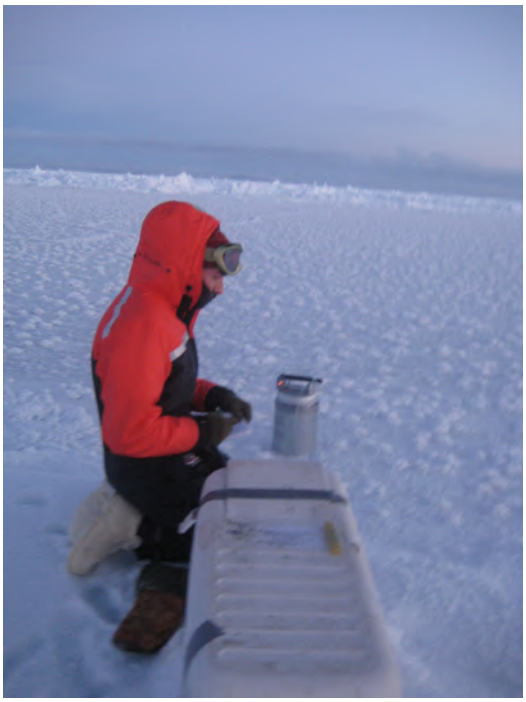

Figure 2.6: Deployment of the flux chamber. Gas analyzer is located in the white cooler.

Sample Dates and Locations

Table 2.3: Deployment dates and locations of flux chamber. All times UTC.

Station	Date/Time	Notes
D2	Nov. 30, 2000	-2 runs on frost flowers
D4	Dec. 2, 1800	-2 runs over frost flowers
D4	Dec. 3, 2300	-3 runs
D5	Dec. 7, 1745	-1 run, poor data results (contaminated?)
D7	Dec. 13, 1656	-3 runs over 55cm FYI

Sample Data

Figure 2.7 shows sample data from a run at station D7 over one hour. There does not appear to be any trend in the data, with CO_2 concentrations varying within 1ppm. This indicates no exchange of CO_2 with the ice. Although all of the data has not been processed, it appears that no fluxes were recorded with this method during the Leg 4 cruise.

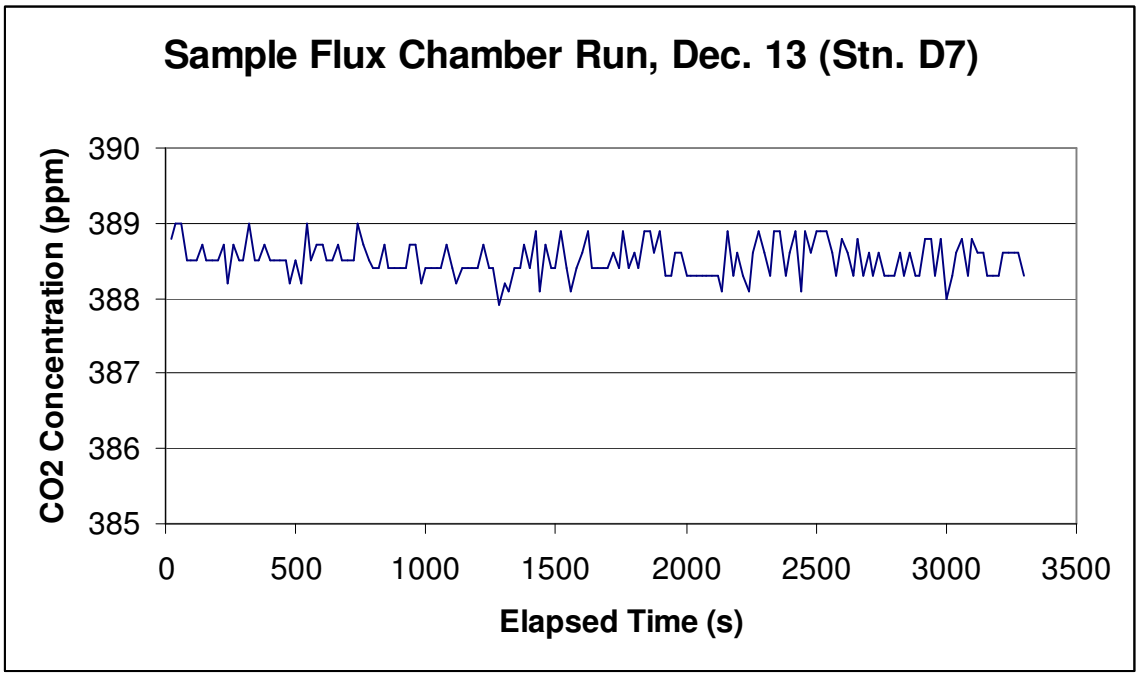

Figure 2.7: Sample flux chamber data over new first year sea ice (approx. 55cm thick).

Flux Chamber Notes
The flux chamber was a fairly reliable piece of equipment during this cruise. In the future, attempts should be made to take measurements over very thin (5-10cm ice) to assess whether fluxes of CO_2 occur over newly growing ice.

2.4.3. Dimethyl Sulphur (DMS) Project

Gauthier Carnat

Introduction
The fieldtrip was conducted during the three weeks of leg CFL 4B as member of Team 6 (gas fluxes). I was the representative of the Belgian team leaded by Dr. Jean-Louis Tison (U.L.B. university, Brussels) and Dr. Bruno Delille (U.L.G. university, Liège) for this leg, the first one we were on. Some other scientists will continue the same work during the next legs until leg 8B.

This fieldtrip was done for a PhD research purpose in University of Manitoba with Dr. Tim Papakyriakou as advisor.

Aim of the study
As a sea ice biogeochemistry team, our main goal is to conduct a study of a various set of biogeochemical variables during the whole CFL experiment (Fig. 3.1.).

Fig. 3.1 List of Variables

List of Variables
Temperature
Salinity
DO18
Thin Sections
DMS,P,O
Total gas content
O2, N2, CH4, Ar, CO2

Nutrients
Chla
Iron and TM

The interest of doing this is double. Firstly, it will give us a good idea of the evolution of these variables through one complete cycle of sea ice growth and melting in a very specific area. Secondly, we will have at the end of the experiment a background of understanding for gases dynamics inside sea ice (minor and major driving factors) with modelling perspectives.

For my own personal project, I was focusing on two climatic effect gases and their dynamics in the sea ice system.

The first one is the carbon dioxide, in close collaboration with Brent Else and Nes Sutherland.

The second one is Dimethylsulfur and related compounds (Dimethylsulphoniopropionate and Dimethylsulfoxyde).

This involves concentration profiles in ice, water and brines and some fluxes measurements as well.

Material and methods

Field measurements

During this early stage of ice formation, our objective was to sample different types of ice at different spots, giving us a spatial and ice type variability. On the other hand, the separation of the measurements inside the three weeks gave us an idea of temporal variability. This one will be reinforced by the next leg's experiments.

We separated our work in main stations (complete set of variables) and punctual sporadic stations (specific set of variables). The next figure gives a description of the stations done.

Fig. 3.2 List of stations

Date	**Type of station**	**Comments**
11/28/2007	Complete	
11/29/2007	Punctual	Pancake Ice (DMS,P,O measurements)
11/30/2007	Punctual	40 cm new ice with frost flowers (Bell measurements)
12/02/2007	Punctual	30 cm new ice with frost flowers (Brines uptake)
12/03/2007	Complete	
12/06/2007	Complete	

On each station we delimitated a clean working area and organized our sampling around three main activities:

1) Ice sampling: we took 11 ice cores for each complete station, using a 7.5 cm diameter corer. The cores have the size of the ice thickness of the considered spot they were taken in. Each core is dedicated to 1 variable or group of variables. A short description of each core (cracks in the core) was made on the field. Most of these 55 cores will be sent back to Winnipeg or Belgium for further analysis.

   Using a temperature probe and a drill, we measured the temperature of the ice on the first core taken on each site every 5 cm starting from 2.5 cm of the surface. In order to have a spatial

coherence, this 5 cm resolution will be used for all the variables measurements. The same first core was then cut in 5 cm pieces and put in Tupperware's to measure salinity back on the ship.

In addition, 15 cores were directly cut on the ship for direct analysis. This concerns the most sensitive variables, subject to quick changes in time.

2) Brine sampling: depending on the ice thickness, we drilled several brine holes as close as possible to the coring site, using a 20 cm spatial resolution. The brine holes were usually drilled in the morning and sampled in the afternoon to give time to the brines to fill the hole. To avoid any gas exchange with the atmosphere, we covered the holes with Styrofoam insulation. Using a small pump or syringes, the brine was pumped out and put in vials for analysis.

3) Water sampling: the water at the sea/ice interface (called 0 m water) was sampled by the use of a pump and weights.

In addition, general observations were made on the field including temperature measurements, freeboard measurements and snow thickness. The next figure shows an example of those observations for one station.

Fig. 3.3. General observations on the field for one station

Variable	Value
Snow Cover (cm)	1.5, new snow
Average Ice Thickness (cm)	60
Freeboard (cm)	5, no flooding
Air Temperature (°C)	-15.5
Snow Temperature (°C)	-14.5
Snow/Ice Interface Temperature (°C)	-14
Water Temperature (°C)	-1.5
Brine Temperature at 20 cm depth (°C)	-10.5
Brine Temperature at 40 cm depth (°C)	-7.8

Post-field analysis

Here below is a list of the variables measured on the ship.

Salinity and DO18

Using a calibrated salinity probe and Tupperware containers filled with ice cut in the field and melted on the ship, we measured the salinity of approximately 50 samples, which represents a spatial resolution of 5 cm for each station. The same water was then used to fill in small DO18 vials for further analysis.

Nutrients and Chl_a

With the help of Kyle Simpson, we did approximately 200 nutrients samples. This represents measurements of NO_2, NO_3, Si and PO_4 at a spatial resolution of 5 cm.

With the help of Dr. Célia Marrasé, the Chl_a level was measured for each station. Considering the low Chl_a levels usually observed in the ice during this time of year (very low light input), we decided to filter melted ice for every 15 cm instead of the usual 5 cm spatial resolution. This represents a total amount of 15 measurements.

DMS, DMSP, DMSO

Using an ice crusher, Dr. Maurice Levasseur's "purge and trap system" and a gas chromatographer, we extracted the DMS from the ice and measured the total amount of DMS at a spatial resolution of 5 cm, for a total of 50 samples. The system was calibrated three times during the whole experiment by using a permeation oven which sends a specific concentration of DMS to the gas chromatographer. Here below is a picture of the ice crusher and of the "purge and trap system" used. In addition, Fig. 3.4. shows the three calibration curves obtained.

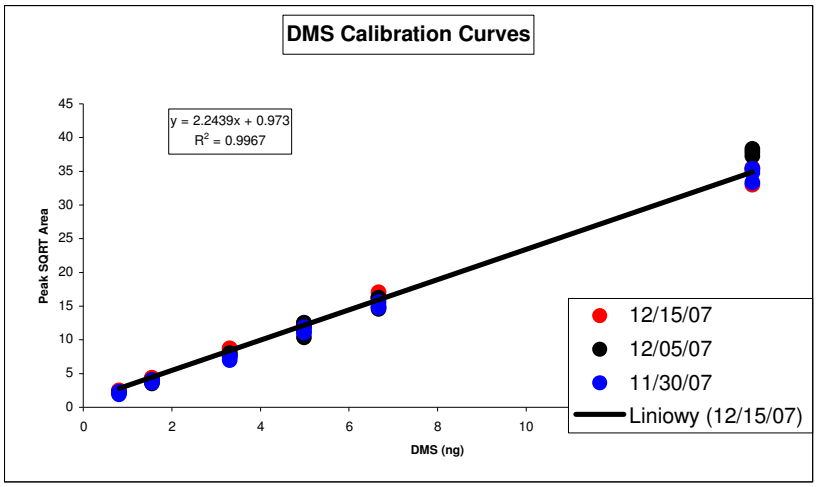

Fig. 3.4. DMS Calibration Curves

By addition of NaOH pellets to the crushed ice, we turned DMSP into DMS and measured 50 concentrations of DMSP. Some ice was also stored in 20 ml vials for DMSO measurements in Belgium.

We measured also DMS and DMSP concentration in brines and 0 m seawater. We've tried to measure levels of DMS in the air just under frost flowers with syringe uptake as well.

Finally, DMS and DMSP levels were measured in two pancakes.

In total, more than 200 samples of ice, water and brines were analyzed.

Other Variables

Additional studies will be undertaken in Brussels or Winnipeg later this year, when the cores come back from the Arctic.

Sample Data

As an example, we show some results and profiles obtained during the cruise.

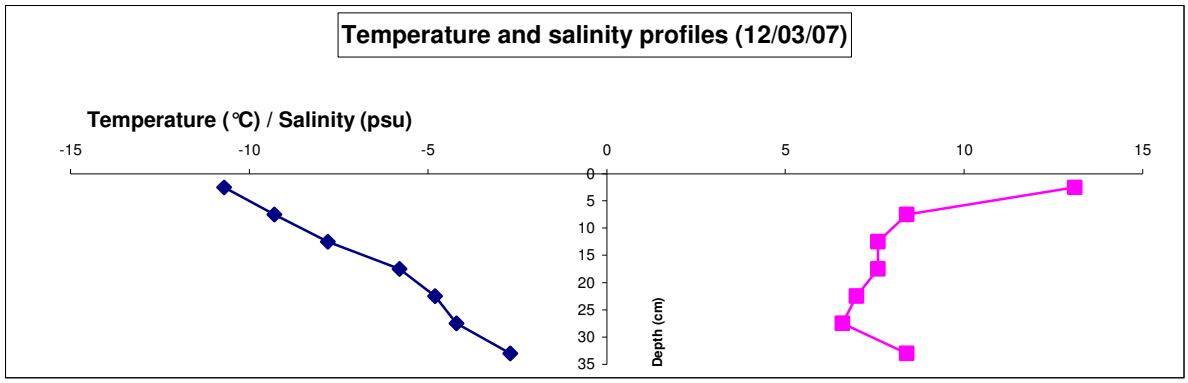

Fig. 4.5. Temperature and salinity profiles for station 12/03/07

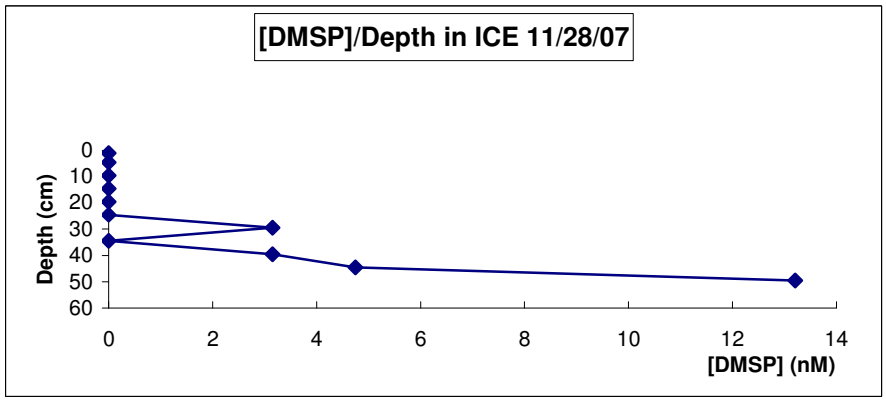

Fig. 4.6. DMSP profile for station 11/28/07

4.6.4 Dissolved Inorganic Carbon (DIC)/Alkalinity Project

Nes Sutherland

Ice Cores and Surface Water Sampling

The study of transfer of carbon through seawater ice is a relatively new field, unfolding over the past five years or so, when it was discovered that seawater ice could actually be permeable to gas exchange, unlike freshwater ice. One tool for studying gas flux is to look at the cores themselves, measuring Dissolved Inorganic Carbon (DIC) and alkalinity in sections throughout the core depth, as well as salinity and temperature for each section. The dynamics of gas flux in the water immediately under the surface is also of interest, as here brines drain out as new ice forms.

This leg was the first one where ice was studied for carbon flux on the Amundsen CFL-IPY cruise, and it was a most interesting period of time to do so, as it was possible to sample ice at almost every stage of development. Some problems were however encountered in attempting to sample young ice, as it was difficult to hold the ship positioned in windy conditions resulting in it drifting over and pushing up layers of ice in the sampling area. As well, work from the cage allowed for minimal manoeuvrability, with it or its door having a tendency to swing. Then there was the risk of the cage dipping into the water! The ideal boat would be the skippy boat, but it was not always available, also due to weather, darkness, the ship being underway, or engine problems…

For roughly the first four weeks of this leg the ship was transiting the area of Franklin Bay, through Amundsen Gulf and up the west side of Banks Island, and back again to the drift site, where the latter two weeks were spent. This resulted in constant sampling of ice cores during the first part, where the many ice types were encountered. Due to the short time at each station it was not possible to sample

for the other carbon flux parameters – brines and peepers, and flux chambers. When finally settled into drift sites, these other parameters could be measured as well, and will eventually be compiled with core data to study the relationship between the different methods.

At each station a team of scientists would be on the ice, sampling various parameters from temperature to microstructure, salinity, biology, and light transmission, as well as carbon. Some of these measurements were intended to be shared amongst the groups, in order to save time and effort in the field. For carbon coring, a minimum of two cores of ~4" diameter were cut at each site, sectioned and bagged in the field to minimize brine loss. In order to focus on the more carbon-active sites, the upper parts of the cores were cut into 0-5, 5-10, and 10-15cm sections, followed by 10cm lengths, with the bottom 5 cm as its own section. Unfortunately it is necessary to have a minimum of 8cm, preferably 10cm, of core length to obtain enough water for filling a DIC/alkalinity bottle, with some remaining for salinity analysis by a handheld conductivity meter. Therefore, the 5 cm lengths were combined in one bag, but the 10 cm sections were individually bagged, and provide a set of duplicates. At some stations snow and frost flowers were also scraped off the surface and into bags. The bags used were Tedlar bags, gas impermeable, with a clamp type seal and small spigot for withdrawing air or water. These bags, although a bit difficult to close when very cold, were very convenient for removing air for melting the core in a relatively air free enclosure – a very small amount of air was always present.

After the cores were processed, surface water samples were taken for DIC/alkalinity, pH and salinity, using a small pond pump. Where possible, water was sampled from just under the surface of water in the core hole, at approximately the bottom of the ice hole, and in the water column, ~1m and ~2m. Not all of these depths were regularly sampled, as sometimes the tubing would freeze. A handheld temperature probe was used for surface temperature, but a portable CTD would have been useful for the other depths.

Back at the lab, the core sections were laid out to thaw, then transferred to DIC bottles, and the remainder saved for the conductivity measurements. For the water samples, the pH's were analysed at 25C using a phenol red and m-cresol purple dye method on a HP8543 spectrophotometer. The DIC bottles were pickled with HgCl and clipped or taped shut. Ideally this would be done in the field, but the HgCl would quickly freeze.

When enough samples were collected, a batch of DIC would be run on the VINDTA 3C – in all about 9 analysis days and 300 samples, running from 12-20 hours at a time. Alkalinities would follow on the TIM 865 Radiometer , with samples sorted by salinity. Two programs were used – one geared for normal seawater, and the other for ice. Further modifications were made to cover very low salinity from multiyear ice, and very high saline brine samples. Unfortunately samples with salinities of less than 2ppth still could not be read. Andrew Dixon Certified Reference Material, Batch 81, was used to calibrate both the VINDTA and the TIM 865, preparing dilutions with Milli-Q water where required for ice samples.

The following table provides a list of stations and cores.

Station	Date	Ice Type	Core Depths (cm) #1	#2	Water	Comments
SH	141107	Core	36	36	3 depths, DIC,pH,sal	SH= Summer Harbour, sampled as a warm up run Bad weather preventing travel to real stations

Rosette Water Sampling

To complete the carbon picture, tying in surface processes with biogeochemical cycling of deep water, DIC, alkalinity and pH samples were also drawn from the rosette at each station, see Table 2. Bottle integrity was first checked by undoing upper vent to test lower seal, then with it closed again, the spigot was opened to see if it leaked. Sampling followed, using established protocols. In general, unless oxygen samples were also drawn, DIC sampling, followed by pH, was done first, to avoid contamination from air. Samples were spiked with 200uL HgCl, and stored in the cold room. Because of the heavy load from ice coring, the water samples were unfortunately not analysed. pH was sampled as described in surface water sampling above.

The following table provides a list of stations and rosette samples.

Station	Date	Cast ID	Samples taken	Comments
1117	151107	005	DIC & Alk, pH	
405	191107	006	DIC & Alk, pH	Bottle 11:poor lower seal
1100	201107	009	DIC & Alk, pH	Bottle 9:poor lower seal
437	221107	017	DIC & Alk, pH	Bottles 6,16, 19:poor lower seal, leaking
1825			No Rosette	Multiyear Ice
1820	251107	019	DIC & Alk, pH	Bottles 11,14:poor lower seal
1812	251107	020	DIC & Alk, pH	Bottles 5,9,11:poor lower seal; Bottle 14 almost empty Oxygen sampled first
420				No Rosette, moonpool clogged with ice, no time to thaw

D1	281107	023 (labelled as 022)	DIC & Alk, pH	Bottle 9:poor lower seal Cast 22 rejected for nutrients due to high welding smoke levels
D4	021207	026	DIC & Alk, pH	Bottles 5,9,14:poor lower seal
D5	041207	029	DIC & Alk, pH	Bottle 22:poor lower seal; bottle 18, spigot leaked
D6				No Rosette
D7	101207	054	DIC & Alk, pH	
D8				Bottles not properly closed due to time constraints Ship returned to Stn D7, but suddenly sent on its way to Sachs Hrbr, without time for a water property cast

2.5. Team 7

2.5.1. Carbon & nutrients fluxes

PI: Jean-Éric Tremblay (Laval University)
Participant: Kyle Simpson (McGill / Laval University)

Rationale
The Arctic climate displays high inter-annual variability and decadal oscillations that modulate growth conditions for marine primary producers. Much deeper perturbations recently became evident in conjunction with globally rising CO2 levels and temperatures (ACIA 2004; Comiso 2003). The thickness and extent of Arctic sea-ice decrease rapidly (Johannessen et al. 1999; Rothrock et al. 1999) and the ice-free season is extending both in the Arctic (Laxon et al. 2003) and subarctic (Stabeno & Overland 2001). Models predict further reductions in ice cover (ACIA 2004). These changes entail a greater penetration of light into surface waters, which is expected to bolster phytoplankton production (Rysgaard et al. 1999), food web productivity and CO2 drawdown by the ocean. At present, phytoplankton production varies by two orders of magnitude across the Canadian Arctic, but the forcing mechanisms are poorly understood and quantified. In the Canadian Archipelago, the productivity of phytoplankton is likely to be limited by light or the supply of allochtonous nitrogen, depending on ice conditions. The supply of allochtonous nitrogen is influenced by climate-driven processes, mainly the large-scale circulation, river discharge, upwelling and regional mixing processes. Over most of the western Arctic, and especially the Beaufort Sea, the concentrations of inorganic nitrogen (i.e. nitrate, nitrite and ammonia) at surface remain low throughout the year and the phytoplankton possibly depend on local recycling and the dissolved organic nitrogen (DON; e.g. urea, amino acids and primary amines) supplied by rivers. A large portion of the phytoplankton biomass is typically located within subsurface chlorophyll maxima (SCM). SCM productivity is possibly in balance with the episodic supply of nitrate across the halocline and/or the supply of ammonium and nitrate by local recycling and nitrification, respectively. Despite the importance of SCM for the food web and CO2 fluxes, little is known about their structure, turnover and susceptibility to environmental variability and change.

Objectives
The main goals of team 7 (nutrients) for CFL were to:
(1) Establish the horizontal and vertical distributions of phytoplankton nutrients and the influence of different processes (e.g. mixing, upwelling and biological processes) on these distributions, with emphasis on the CFL over-wintering "drift area"
(2) Process and analyze the backlog of samples acquired during the final legs of ArcticNET and the previous legs of CFL
(3) Experimentally assess the production of nitrite (nitrification) by bacteria

Methods
Samples for inorganic nutrients (ammonium, nitrite, nitrate, orthophosphate and orthosilicic acid) were taken at all rosette stations (see Table 1) to establish detailed vertical profiles. Additional samples for dissolved organic nitrogen (DON), dissolved organic carbon (DOC) and urea were taken at the same stations. Ammonium was determined immediately after collection using modifications of the manual fluorometric method (e.g. Holmes et al. 1999). Urea samples were analyzed immediately and DON/DOC samples were preserved with acid and stored in the dark at 4°C for post-cruise determination. The concentrations of nitrate, nitrite, orthophosphate and orthosilicic acid were determined on fresh samples using an Autoanalyzer-3 (Bran+Luebbe) with colorimetric methods adapted from Grasshof (1999).

Incubation temperature (nitrification experiment) was maintained at *in situ* levels with a chilling circulator. Samples from all modules were spiked with 13C-bicarbonate; modules received saturating additions of, ^{15}N-ammonium, one of two inhibitors and were incubated in either dark or light conditions. Samples for nitrite concentration were collected at 6hr intervals for the determination of utilization/production kinetics. Incubations were terminated by filtration onto 24-mm 0.2µm silver filters. All filters were desiccated at 55°C and stored dry for post-cruise determination of isotopic enrichment and particulate organic carbon and nitrogen.

Samples taken
All Stations were sampled for nutrients in the water column. (see rosette log)
Surface water, and water under the surface of the ice was sampled when available.
Ice samples were also processed.

2.5.2. Molecular Microbial Biodiversity

Participant: Pierre Galand (Connie Lovejoy's group), Québec Océan, Département de Biologie, Université Laval, Québec

Introduction and cruise objectives
Microorganisms, including bacteria, archaea, viruses and micro-algae, were until recently very difficult to describe. Their distribution and role in the sea was unknown due to their small size and the

difficulty in isolating and culturing them. With the development of molecular tools targeting the DNA of those organisms, we are now able to uncover functionally diverse microbial communities within the Oceans.

Our first objective was to collect microbial DNA and ancillary data from the Amundsen Golf and Beaufort Sea to detect possible interannual variability at stations sampled earlier and to compare the microbial diversity between those different regions.

Our Second objective was to obtain RNA samples from the same sites to investigate expression of key genes during the winter and under different oceanographic conditions. Our initial work in this area will be to compare diversity, relative abundance and expression of bacteria and archaea AmoA genes. This gene is expressed during nitrification of (ammonia towards nitrate) and codes for a key nitrogen cycling enzyme in the world ocean.

Our third objective was to conduct short term experiments aboard the vessel to enlarge our understanding of the active microbial processes taking place during the winter season. In particular we used a technique known as Stable Isotope Probing (SIP), where flow of carbon through active microbial communities can be studied with the incorporation of stable isotopically labeled substrates into biomass and subsequent identification of the microorganisms actively incorporating the label.

Sampling

We sampled on an opportunity basis throughout the Amundsen Golf and the Beaufort Sea (coast of Banks Island). The comparison of samples gathered during the different wintering legs will allow a better understanding of the seasonal dynamic and the comparison of the different geographical areas will provide valuable information on the diversity and depth distributions of microbes.

In total we sampled 12 stations (Table 1), where a total of 10 variables were collected (Table 2). Our sampling strategy was to obtain microbial DNA and other biological data from specific water masses through the water column with a special focus on the nitricline, the upper mixed layer, the Chlorophyll maximum and deep temperature maxima and minima. Those biologically significant features were identified during the downcast of the CTD. In addition to temperature and salinity, our sampling choices were based on readouts from the oxygen, nitrate, fluorescence, transmissometer and ph probes.

Table 1. Stations sampled for our DNA group.

MMBOAS Stn	Cast nb	Station Name	Date	nb depths	Latitude (north)	Longitude (west)

Sampling was aimed at obtaining microbial DNA and RNA along with biomass and taxonomic information. All variables were sampled using standard techniques.

Table 2. Variables and number of samples taken.

Type of Sample	number of samples
DNA (<3um)	43
DNA (>3um)	43
RNA (<3um)	42
RNA (>3um)	42
Chl a T	43
Chl a (<3um)	43
HPLC Total	19
HPLC (<3um)	19
FISH B & A	4
FISH Eukaryotes	4

Abbreviations and explanations follow: Chlorphyll *a* (Chl a), pigment analysis by high pressure liquid chromatography (HPLC). Fluorescence in situ hybridization (FISH) will be applied to Bacteria, Archaea and eukaryotes (FISH B & A and FISH Eukaryotes, respectively).

Experimental program

SIP (Stable Isotope Probing)

SIP is an elegant tool to resolve the linkage between the structure of populations and their function in an ecosystem. The principal rely on the addition of labelled substrate highly enriched in stable isotopes, such as ^{13}C, to an environmental sample. The denser isotopes are incorporated in the nucleic acids deoxyribose backbone of the organisms utilising the labelled substrate as growth substrate. The denser DNA or RNA is then separated from the light one (non labelled) by caesium chloride (CsCl) density-gradient centrifugation. Finally, once ^{13}C -DNA has been isolated, it can be analysed by various molecular methods allowing the phylogenetic identification of the organisms which assimilated the labelled substrate.

On board, incubations with ^{13}C – bicarbonate were carried out to study the flow of carbon during winter time. Surface water was incubated with the presence ^{13}C – bicarbonate. And incubations were placed in the dark to simulate winter darkness. Over a five weeks period duplicate bottles were periodically filtered for DNA and microscope analysis. The results should provide information on species specific interactions in the flow of carbon through the microbial community.

Results

Since it is currently not feasible to analyse DNA or RNA on board the ship, results of the DNA and RNA surveys will be known only after extensive laboratory work on shore.

Acknowledgements

The cruise was a success and we are grateful to the Chief Scientist, Captain and crew of the Amundsen. We would like to thank M-É Rail and H. Drouin for CTD Rosette operations, S. Blondeau for technical assistance and K. Simpson for nutrient analysis.

2.5.3. Marine Molecular Microbiology Group

Participant: Cèlia Marrasé (Carlos Pedros-Alio's group), Institut de Ciències del Mar (CSIC) – Barcelona, Spain

Our objective is to find empirical relationships between the physical and chemical variables and the diversity and function of the microbes. We are also carrying out this type of study in areas of the Mediterranean and Antarctic seas, and Atlantic Ocean.

Here in the Arctic, the distinctive factors are: the lack of light during part of the year, the low temperatures and the ice cover. Comparing the species composition and activities of microbial communities in systems with diverse chemical and physical regimes is a good way to learn more about the importance of the different forces that determine how microbes use organic and inorganic matter and how this influences other components of the food web. This knowledge is needed to better predict the consequences of natural or anthropogenic changes on these trophic dynamics – or in other words, on the biological production of the system. This will also help us to evaluate the system's ability to buffer these changes at short and long time scales.

During Leg 4 water samples for different biological and chemical analyses were taken: dissolved organic carbon, amino acids, carbohydrates, f-DOM, chlorophyll, FISH Eukaryotes, nanoflagellates, virus, and ciliates. We also performed incubations to quantify bacterivory, and virus diversity and production. I summarized the number of samples and stations in Table1.

Finally I want to thank the Chief Scientists and the Capitan for facilitating our sampling wishes, and to all the crew for being so nice and helpful. They made possible an excellent atmosphere.

2.5.4. Bacterial Processes

PI: Roxane Maranger
Participant: Gabriel Maltais-Landry

Scientific Objectives CFL: As part of team 7, the goals of this team are to measure bacterial C production, community respiration (directly and via ETS activity) and bacterial biomass, in order to elucidate the role of bacteria in ecosystem C processing. Another objective for CFL will be to measure N_2O concentrations in the water column to understand whether this by-product of nitrification and denitrification accumulates at a measurable rate in this system.

Objectives Leg 4: The main objectives were to start sampling on a regular basis and adjust method if need be. Priority was given to the future drift site, but measurements were carried out at several stations outside of this area. Supplementary measurements (bacterial production in melted ice and in water used in grazing experiments) were also carried out.

Bacterial production

- Bacterial production rates were measured using the leucine incorporation method (^{3}H labelled leucine) with 4 hours of incubation at 2°C. Rates of incorporation of radio labelled leucine were then converted into rates of C production.
- Bacterial production rates in the water are low but measurable.

- Bacterial production in the ice seems negligible, at least in the cores we sampled on this leg. Future measurements should be carried out in spring.
- Bacterial production doesn't seem to be significantly impacted by 48 hours of incubation at 2°C.
- Bacterial production rates seem higher near Sachs Harbour (stations 437, D4) and lower at the northwest of Banks island (stations 1812, 1820) than at the other sites (1117, 405, D1, D7, D8).

Bacterial respiration

- Bacterial/community respiration rates were measured using the FIBOX, which measures O_2 depletion in time using sensors glued to the bottom of 500ml Erlenmeyers. The consumption of O_2 in time can be converted in CO_2 production to compare C respiration rate to bacterial C production rate.
- Respiration using the Fibox is difficult when the ship is moving because of sensor alignment problems. However, during the second part of the leg, when the ship was more stable, measurements were carried out with relative success.
- Incubations are pretty long (> 14 days) and instability in cold room temperature can have adverse impacts on measurements. However, chamber temperature stability problems and set up of incubating coolers seem to be okay for now.
- Respiration rates are higher in the surface (10m) than deeper in the water column. In deeper depths, rates are sometimes not measurable. We have too little data on spatial variability for now to state on differences between stations.

ETS

- Due to really low respiration rates in Arctic waters, a back-up method was also employed to obtain respiration rate surrogates via ETS (Electron transport system activity). This is achieved by filtering a large quantity (8L-10L) of water on GF/F filters to collect live cells and freeze them (-80°C) as quick as possible. Back at the lab, we will defreeze these filters and subject the living cells to various enzymatic tests to measure activity.
- Due to the difficulties we have obtaining respiration rates at deeper depths, more efforts were given to ETS filtration as a back-up for respiration.
- Filtrations for ETS were carried out and the fine tuning of the filtration procedure was accomplished. Samples were put in cryovials in the -80C freezer for analysis back in Montreal when the ship gets back to Quebec City.

Bacterial abundance

- Bacterial abundance can be estimated by filtering a small volume of water (20ml) fixed with formaldehyde that has been stained with DAPI (bounds DNA). Slides are then frozen (-20°C) and counted for abundance using 20 random fields.
- Bacterial abundance filtration and slide making has started and the slides were made for all the stations monitored during the leg.
- Counting could not start because no grid was found onboard for the microscope. The slides are still inside the -20°C freezer in the aft labs.

N_2O

- Dissolved N_2O measurements were carried out using the headspace equilibration method with 1.1 L of seawater. 3 samples were taken from each bottle (depth) and will be analyzed at the lab for N_2O on an electron capture detector (GC).
- N_2O measurements were carried out more often than originally planned and the sampling method was refined to get 3 depths rather than 2 depths.
- The plan to do one intensive profile (6 depths) was abandoned due to the need to get out of the drift site quickly at the end of the leg.
- Samples were taken at the end of the leg for analysis (GC) in Montreal.

Other activities

2007/11/08 – 2007/11/15: inventory, lab setting up, waiting for ship to finish refuelling and board cargo.

2007/11/15 – 2007/12/18: help given to different teams for ice work, balloon launches and nutrient sampling at the rosette in addition to regular sampling activities.

2007/12/18 – 2007/12/20: lab (s) clean up, final wipe test, inventory of materials used, and filmmaking of protocols for future members of team 7.

2.6. Team 8

2.6.1. Organic contaminants

PI: Gary Stern (DFO, Freshwater Institute)
Participants: Bruno Rosenberg (DFO, Freshwater Institute)
Monika Pucko (PhD student, University of Manitoba)

Hexachlorocyclohexane (HCH)

Water sampling
Water (4L) was collected from the rosette at all full and basic stations. At the surface, a plastic bucket was used to collect the water. Where feasible, transects across water bodies were collected. In the lab, water was pumped through a glass-fiber filter followed by an ENV+ solid-phase extraction (SPE) cartridge using peristaltic pumps. On ArcticNet leg 3/CFL leg 1, we collected 29 profiles, usually

consisting of 9 depths, with the emphasis on the upper water column. Filters and cartridges are frozen and brought back the Freshwater Institute for analysis. $^{18}\delta O$ and salinity samples were also collected at each site and depth where HCH samples were taken.

Air Sampling

The air sampler was set up on the bow of the ship on the starboard side for all full stations, most basic stations, and several transects. Samples are collected on a glass fiber filter and polyurethane foam (PUF) for analysis of organic contaminants. Air samples collection time ranged between 4 and 23 hours. A total of 32 samples were collected. Filters and PUFs were frozen at -20°C and shipped frozen back to the FWI for HCH contaminant analysis.

Ice sampling

Ice samples for HCHs concentration and enantiomeric composition were collected at each basic and full station where the newly formed ice was present (Table 1). The samples for oxygen isotope composition ($\delta^{18}O$) and salinity were taken along with all ice samples. The ice samples were collected in collaboration with team 2 and the ice microstructure and physical analysis was made on all of them (see team 2 cruise report). The total of 7 samples of newly formed sea ice and 1 sample of 1m top layer of multiyear sea ice (MYI) for HCHs, $\delta^{18}O$, physical data and microstructure analysis was collected.

Table 1 Ice sampling locations for HCHs during leg 4A

Date	Station	Type of ice	HCH sample #	$\delta^{18}O$ sample #
12 Nov 07	REF	FYI, fastland homogenous ice taken very close (500 m) to the shore during refuelling in Sommer's Harbor; 2-3 cm of snow on top and a thin slushy layer	AN07-LV-351	364
15 Nov 07	1117	Landfast FYI, 2-3 cm snow on top, hard surface	Ice 1	372
16 Nov 07	1117	Landfast FYI, 2-3 cm snow on top, hard surface	Ice 2	373
19 Nov 07	405	FYI with huge conical frost flowers and no snow on top	Ice	391
20 Nov 07	1100	Consolidated pancake ~5cm with slushy layer (white) on top	Ice	392
20 Nov 07	STU	FYI (~45 cm) with huge conical frost flowers covered by white (snow?) layer	Ice	402
22 Nov 07	437	FYI (~58-67 cm) with huge conical frost flowers covered with 1 cm of snow	Ice	404
24 Nov 07	1825 (MYI)	MYI (~3.3m in the refrozen melt pond), mixture of refrozen melt pond cores and hummocks taken; covered with snow – 10-15 cm; only top 1m cores taken	Ice	414

Ice samples were collected from the ice cage. When the ice was thin enough, the ice chipper was used. In case of thicker ice (>15 cm) the ice cores were taken. The total of 4-8 L of melted ice was pumped through a glass-fiber filter followed by an ENV+ solid-phase extraction (SPE) cartridge using

peristaltic pumps. The cartridges and GFFs were stored in -80 °C and brought to the DFO (Winipeg) for further chemical analysis.

Perfluorooctanoic acid (PFOA) and perfluorooctane sulfonic acid (PFOS)

PFOA and PFOS are the two major perfluoros present in North Atlantic waters. They range in concentrations from <10 to 500 pg/L. Previous work has shown that they are present in somewhat higher concentrations in near shore waters sampled around Nain (June and September 2006) and Resolute Bay (June 2006). In this sampling program we hope to obtain a detailed picture of PFOA and PFOS concentrations in near shore and open ocean sites to test our hypothesis that concentrations follow a declining gradient away from land.

Flourinated materials are found in a wide range of applications because of their unique stability toward redox agents as well as for their inert and nonadhering surface properties. They are used in many commercial products such as paints, polishes, packaging, lubricants, firefighting foams, cookware, and stain repellents. During the past six years, scientists and consumers became more aware of these materials when 3M, a longtime major manufacturer of these compounds, declared that it was stopping production of some perfluorinated compounds, including PFOS and PFOA. The primary reason for withdrawing PFOS from the marketplace was the discovery that it is persistent, bioaccumulative, and toxic in animal studies. The U.S. Environmental Protection Agency subsequently requested more information on PFOA to ascertain the sources of human exposure and to determine the environmental effects.

PFOA and PFOS are likely present as residuals in polymers used on the ship because of past use as stain repellents, floor polishes, lubricants in Teflon (PFOA only) and therefore could be sources of contamination, especially in ship and lab air. Water was collected off the rosette through norprene and tygon tubing directly into polyethylene containers to limit contact with ship air as much as possible. Other possible sources of contamination to be avoided are Teflon tubing and bottles, Gortex or other stain repellent coated clothing, possibly KimWipes and waterproof paper.

Between 1 and 2 L of water was pumped through 6 ml (150 mg) WAX solid phase extraction cartridges at a flow rate of 10 ml / minute using peristaltic pumps. The cartridges were preconditioned (July 18) and shipped dry in 50 ml polypropylene vials, sealed with parafilm wax. Prior to filtration, the cartridges are spiked with 50 µl of an internal standard made up of 11 PFC's. In order to avoid air contamination during filtration, an additional WAX cartridge packed with polyurethane foam was used as an air filter. After filtration, cartridges are returned to the polypropylene vials, resealed with parafilm and refrigerated at 4 C.

Water blanks and cartridge recovery checks were performed to identify contamination sources. As an additional check of on-board collections and extractions, duplicate water samples were collected at a number of stations. These duplicate water samples will be sent back for extraction in a clean room setting for comparison to ship extraction.

Water was collected in depth profiles using a plastic bucket for surface water and the rosette for 5, 10, 25, 50, 100 and 200 meters at 2 stations (111, 435). A spatial study was also conducted with water from 5 m (rosette collection) at 9 stations (134, 301, 302, 305, 308, 309, 310, 314, and 434).

2.6.2. Biotic Sampling (mercury, stable isotopes)

The main purpose of this study is to link physical and biological processes to mercury levels in the food web and to target the pelagic food web biomagnification and bioaccumulation of mercury with stable isotopes and fatty acids. Thus, all biological samples collected will be measured for total mercury and MeHg along with stable isotopes to place organisms into their associated trophic levels.

Biological samples were collected at every basic and full stations along the cruise transect. Various zooplankton families and fish samples were collected using the vertically towed Monster net Monster net (200 and 500 µm), an oblique Tucker net (2x500 µm) and the RMT (rectangular midwater trawl, 1600 µm). Zooplankton and fish were sorted into families, placed into plastic vials and Whirlpak bags and frozen until they can be analyzed for THg, MeHg, stable isotopes and fatty acids. Zooplankton was collected at 32 stations. Many thanks to the University of Laval zooplankton team for hard work out on the foredeck.

Additionally, total body length (the distance from the front of the head to the tip of the longest uropod) of the individuals of the hyperiid specie *Themisto sp.*, an amphipod highly distributed throughout the High Arctic was measured to the nearest 0.5 mm. Animals greater than 18 mm are considered adult and smaller than that free living juvenile. The individuals were divided into size classes; 0-10 (newly hatched individuals/Juvenile 1), 11- 15 (Juvenile 2), 16-20 (1 year old immatures), 21-30 (individuals of over 2 years old), >30 and whenever possible, separated into different vials as described above.

Leg 5

21 December 2007 – 31 January 2008

edited and compiled by Tim Papakyriakou and Jody Deming (Chief Scientists)

1. General overview

1.1. Introduction

Leg 5 began with a successful crew change from Inuvik on 20 December 2007 (Table 1) and soon included celebration of the Christmas holiday and the arrival of the New Year (and later the arrival of the Sun!), bringing all participants, from a wide range of countries and cultures, together in a unique way. Logistically, Leg 5 saw the continuation (from Leg 4B) of the 'drift-mode' component of the CFL experiment. In this mode, our requirements were to use as little fuel as possible, while still maintaining some presence in and around the Amundsen Gulf polynya. We learned early in the leg that the weekly fuel allotment was readily exceeded when conditions required sustained ice-breaking through thick ice. Fortunately, we were able to "recover" such over-expenditures of fuel by drifting with an ice floe for more than a week; a drift time of 9 days on a floe initially at >60 cm ice thickness proved optimal for science and for fuel conservation. At the end of the leg, we were pleased to leave the project "in the black," having used less than our overall allotment of fuel (by 22 m^3).

Regarding maintaining a presence in Amundsen Gulf, initial attempts to establish a sampling circuit that included periodic access to the polynya and prolonged station stops in zones of 'slow' drift, usually close to shore in the lee of Banks Island, were not successful in terms of fuel conservation. The prevailing winds and currents within and around the polynya were easterly during Leg 5A, resulting in a strong westward flow of ice in Amundsen Gulf. We learned that in high winds the drift rate west could be fast enough to pose both a fuel problem and a hazard to science operations. The necessarily short residence time on a rapidly drifting floe did not justify the fuel consumed trying to maintain a presence in the Amundsen Gulf, nor could the moon pool be opened when ice was actively rafting. The ice can be pushed under the ship's bow, floating up into the opening (as experienced on New Year's Eve) or can be so large as to block descent of the rosette even though the moonpool appears entirely free of ice by visible inspection (as experienced during Leg 5B). We also could not safely establish on-ice sampling (with equipment left in place) when conditions were so dynamic. Our initial compromise was to tuck the ship up to the lee of Banks Island, where the drift rate was slower, allow drift north and west, then re-establish position to the southeast. This approach worked as long as the prevailing winds drove us to the northwest. Partway through Leg 5B, the prevailing winds shifted after a notable storm bringing 40-knot winds and our drift became southeasterly, easing the situation from several perspectives.

Accumulated experience from this leg yielded the following criteria for selecting a suitable floe: an initial ice thickness > 60 cm, measured by augur during a reconnaissance flight (90-100 cm worked well, < 60 cm did not); areal dimensions adequate for an airstrip (if needed in emergency or for an impending crew change); and surrounding ice conditions that were relatively safe (no immediate multi-year ice or else buffering first-year ice around the floe). Ultimately, we completed this leg with

a slow drift station (D19) in the southeasterly direction, on which the crew change for Leg 6 successfully took place, accomplishing the Leg 5 science program with near-100% success, as evidenced by the team cruise reports that follow.

1.2. Science Personnel

*disembarked one day early (on return flight that had brought Leg 6 OASIS team members to the ship), to look after science cargo sent on same flight.

1.3. General Operational Log and Cruise Track

The Google-Earth cruise map below (Fig. 1) captures both the initial expectations for location of Leg 5 work and the realized outcome. The white rectangle is an ideal sampling location by original project plans (superimposed on the cruise track of an earlier mobile leg), while the red rectangle is the compromise region given fuel limitations and safety issues. The next map (Fig. 2) details, as an example, the floe-track of drift station D17 (Leg 5B). It shows the directional shift to the west, towards a more rapid flow zone, which occurred on day 8 and was part of the rationale to leave this site. Subsequent floe-tracking using satellite imagery, conducted by ice specialist André April on board, revealed that D17 was compressed into ridged ice by encroaching multi-year ice within several days after our departure. Judging the choice and location of floes post-D17 was facilitated in part via the use of ice beacons, originally intended for deployment on multi-year ice floes to track them through their lifetimes (see Team 2 report). Three of these beacons were deployed within the selected drift area at the start of Leg 5B (Fig. 1), two on multi-year floes (which remain deployed) and the third on a first-year ice floe that resembled those often selected for drift stations, in order to monitor the separate movements of these different ice types in the immediate region. The strategy served us well, perhaps especially after we lost contact with the third beacon. Identifying the reason for its loss (a lead opened beneath it; Fig. 3) helped direct us away from inshore floes. Accordingly, our final drift station D19, was offshore from previous selections (Fig. 4).

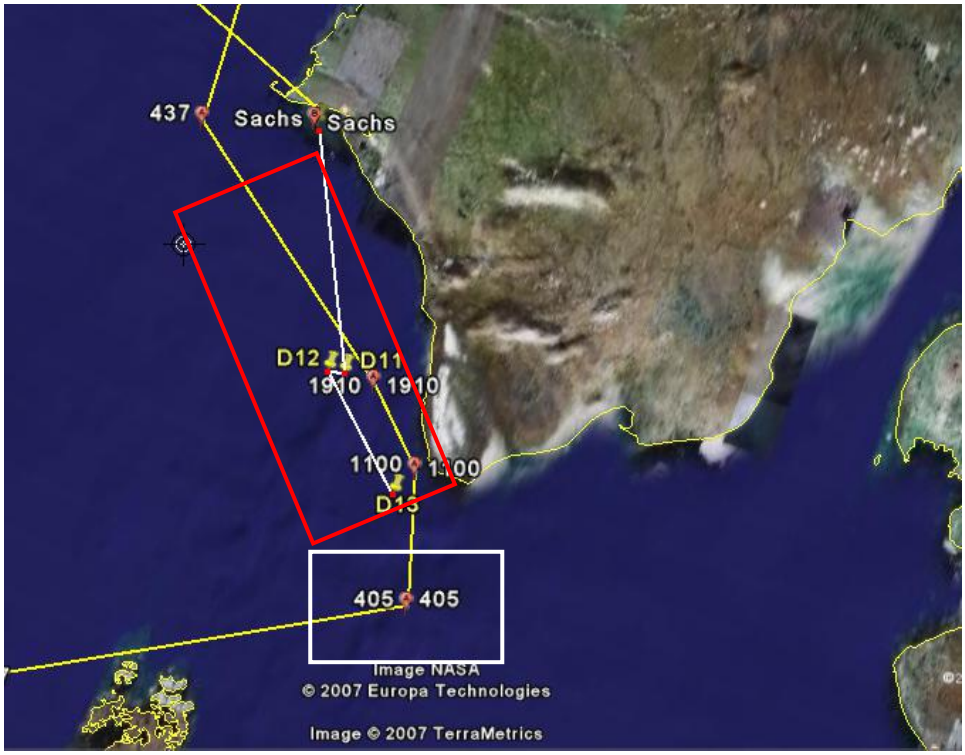

Fig. 1. Google-Earth map showing cruise track during previous mobile Leg 4A and drift-mode Leg 4B (yellow/white lines), the ideal sampling area for drift-mode legs based on original project plans (white box), and the realized area during Leg 5 (red box).

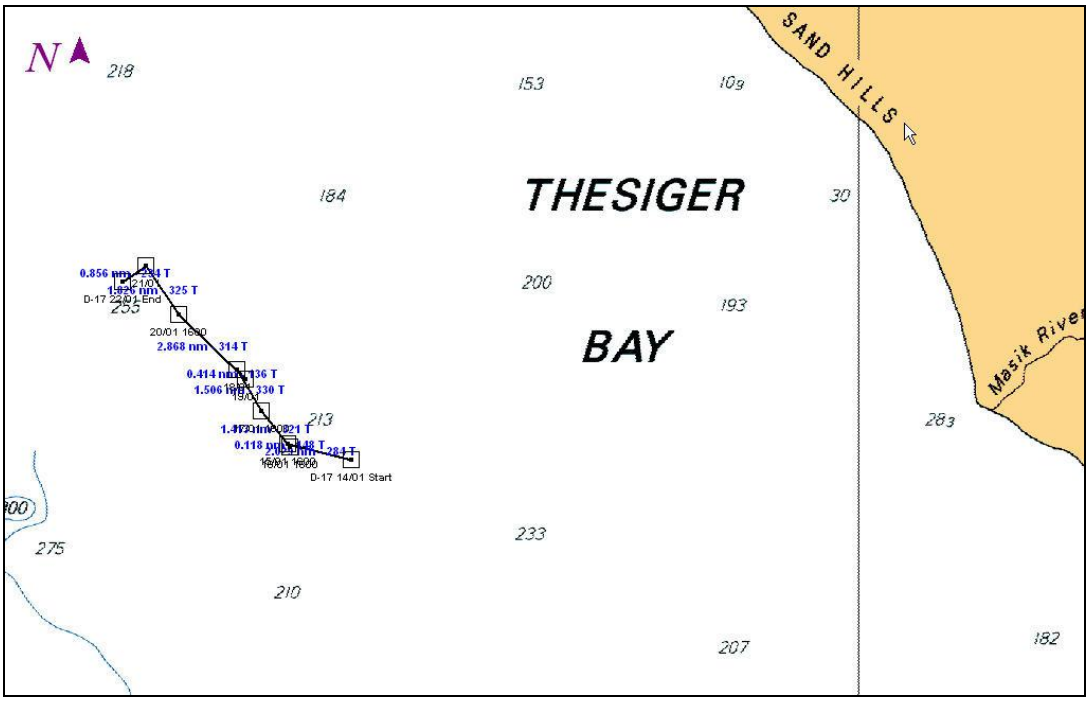

Fig. 2. Daily coordinates (boxed black dots) of drift station D17 (Leg 5B), showing shift on day 8 to the west/southwest, towards a more rapid flow zone, contributing to the decision to leave this floe (map prepared by 2nd lieutenant David Carpentier).

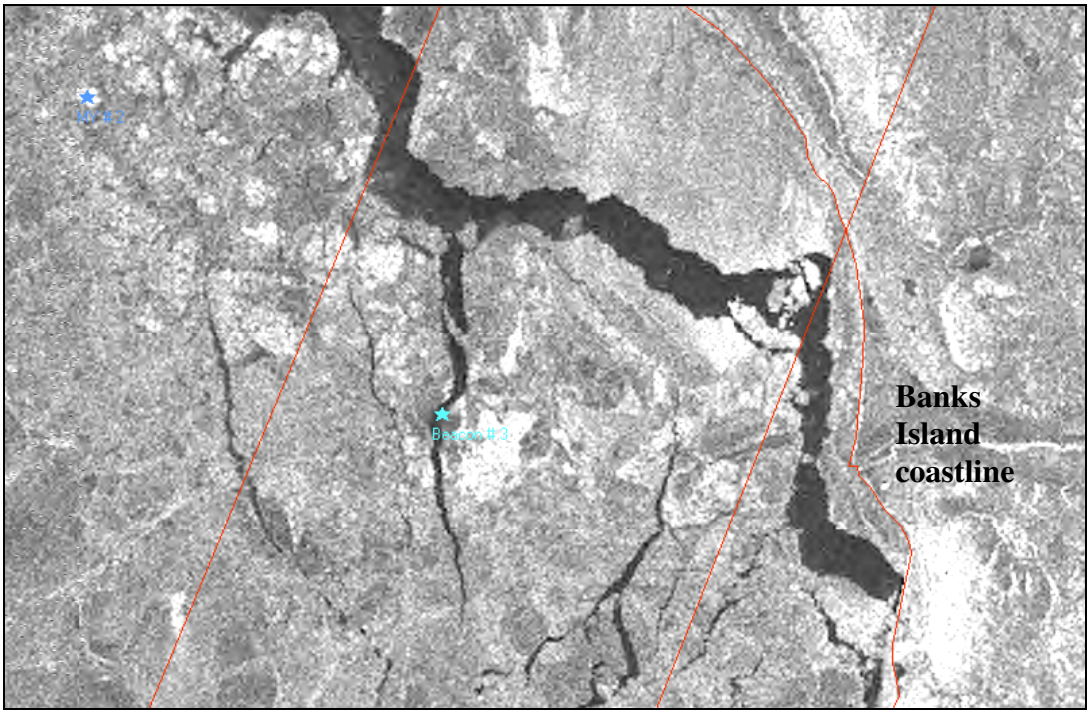

Fig. 3. Radarsat image of the drift-station region (on 21 January) showing two (of three) beacons deployed to facilitate drift-station selection: beacon #2 (blue star, upper left) still on its multi-year floe and the expected location of beacon #3 (aqua star in center) after losing contact with it (map prepared by Chief Officer Michel Dufresne).

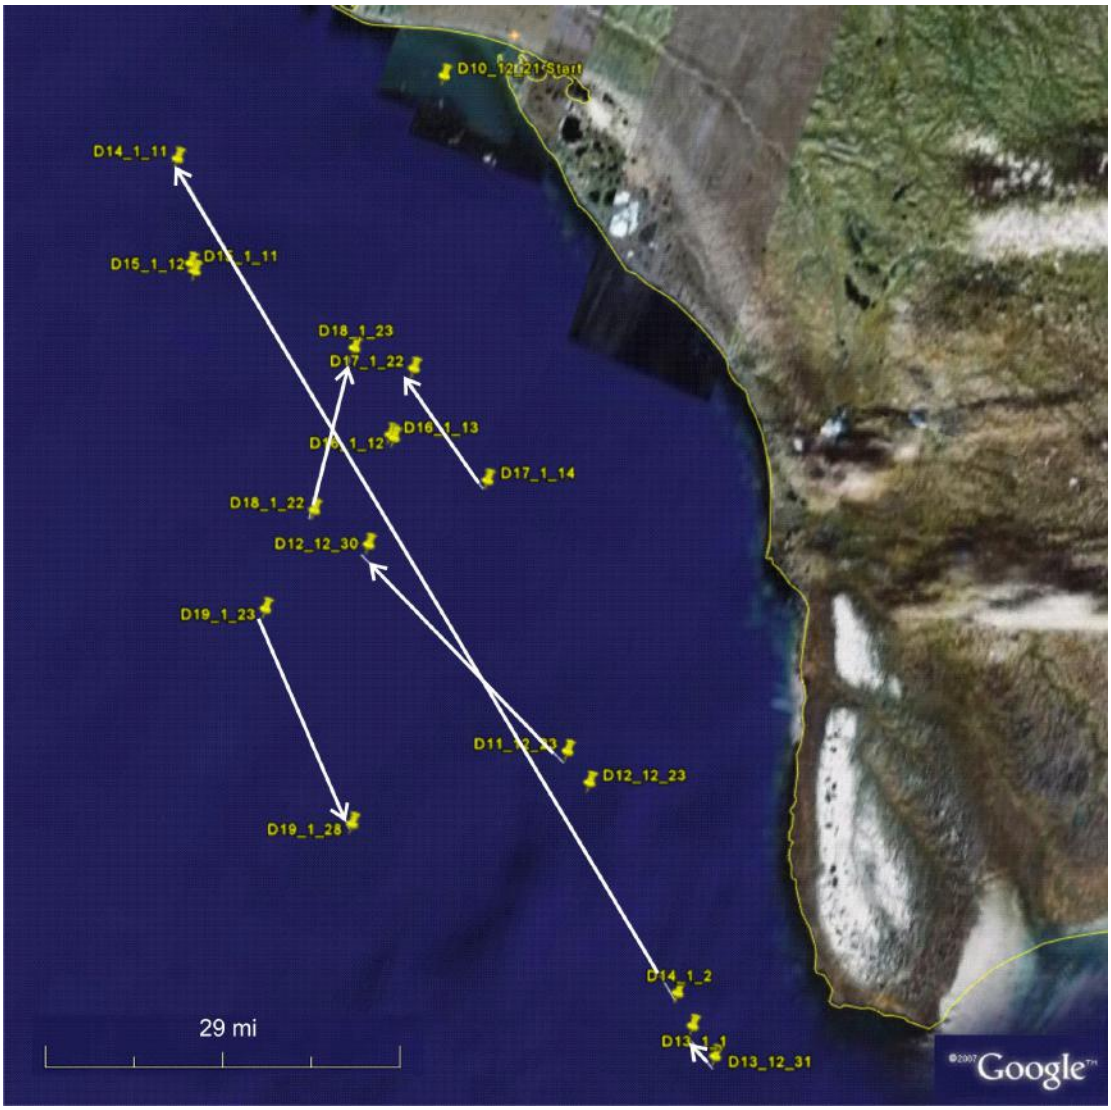

Fig. 4. Google-Earth map showing Leg 5 drift tracks for stations D11–D19.

During Leg 5, we followed the nomenclature for naming drift stations that was established during Leg 4B. For example, 2008D14 was the 14th drift site since the start of the program. The previous site was 2007D13. The main (long residence time) drift stations during Leg 5 were 2008D14, D17 (Fig. 2) and D19, with 5–9 days spent wedged into the floe for full science operations in the moonpool and on the ice. The repositioning effort between drift stations, once we acquired sufficient experience and began to occupy the compromise region (Fig. 1), typically required two days. During transit, we would park overnight at a floe, largely due to the winter darkness of our leg which made moving the ship at night problematic in terms of avoiding heavy ice (and thus conserving fuel). This and other darkness-related challenges were largely relieved once the sun came over the horizon on January 26, near the end of Leg 5. Our "forced" overnight stops enabled science operations from the moonpool and from short-term operations on the ice, so that these floes were also given full station designations. The related transit periods provided for critical (and CFL-unique) sampling of the various stages of freshly forming ice from the cage (see front-page photo). New-ice samples collected during transit were linked to the overnight drift station. A listing of our sampling sites, with location and time on station, is provided (Table 2), along with a Google-Earth map that depicts all of the drift stations of Leg 5 (Fig. 4). The ship's log of science operations as recorded on the bridge is also provided in its entirely (Table 3).

The trade-offs between conserving fuel, keeping the ship in a desired location (for science operations or crew changes), and meeting science goals definitely presented challenges during our leg. We

attribute the overall success of our leg to the conscientious and dedicated work of the men and women of "équipe B." Commanding Officer, Lise Marchand, and Chief Officer, Michel Dufresne, acted with skill, grace and good humor, often under duress, meeting and exceeding the demands placed upon them. Their junior officers brought an important enthusiasm to the effort. Chief Engineer, Richard Bourdeau, and his team ably kept the ship functional in all its capacities as only he could, knowing the ship since its first design-days as a vessel for science. Bosun, Jacques Claveau, proved his worth from day one, as did all members of the crew who worked cheerfully alongside the science participants to accomplish our goals. We especially thank those who served as gun-bearers on the ice (including the Chief Officer), along with scientists Andrea Niemi, Debbie Armstrong, Jeff Latonas, and Dustin Isleifson. Head chef, Jacques Vézina, and his talented team turned the holidays away from home into special memories and continued to feed us creatively even as fresh supplies dwindled. Logistics officer, Lucie Bouchard, and her associates managed an effective stocking of the ship, while our nurse, Marie-Paule Carriére, kept us as healthy as possible in the face of winter colds and such. We stop short of naming everyone only in the interests of space, but speak for the science party in extending our sincere thanks to each and every member of "équipe B" for their essential roles in the success of Leg 5.

2. Team reports

2.1. Team 1

2.1.1. CTD/Rosette

PI: Yves Gratton
Participants: Loïc Degroote, Véronique Lago (INRS-ETE, 490, Rue de la Couronne, Québec)

Objectives
Description of water masses and general circulation over a year in Beaufort Sea and Amundsen Gulf.

Materials
Physical parameters were recorded using a ship mounted RDInstruments Ocean Surveyor ADCP (150kHz), and a rosette frame equipped with 24 bottles of 12 L and the following sensors:

Table 1: Sensors used on the Rosette.

Photo	Item	Manufacturer	Type & Properties	Serial Number
	Nitrates	Satlantic	MBARI ISUS Range: 0.5 to 200 µM Accuracy: ± 2 µM	134
	PAR	Biospherical		4664
	SPAR	Biospherical		20147
	Fluorometer	Sea Point		2465
	Transmissometer	WetLab	Path length: 25 cm	CST-558DR
	Altimeter	Benthos		1061

	CTD	SeaBird	SBE-911 Sampling rate : 24 Hz	
	Temperature	SeaBird	SBE 3plus Range: –5°C to + 35°C Accuracy: 0.001	4204
	Pressure	SeaBird	Accuracy: 0.015% of full range	90584
	Conductivity	SeaBird	SBE 4C Range: 0 to 7 S/m Accuracy: 0.0003	2696
	Oxygen	SeaBird	SBE-43 Range: 120% of saturation Accuracy: 2% of saturation	0427 (cast 1 to 73) - 0420 (cast 74 to 158)
	pH	SeaBird	SBE-18 Range: pH from 0 to 14 Accuracy: pH 0.01	0444

Methods

For the whole leg, because of heavy ice conditions, the rosette was deployed from the Moonpool. CTD or Rosette casts were usually performed four times a day at 7 a.m., 1 p.m., 7 p.m. and 10 p.m. Four times, we did a 14 or 15 hours non-stop CTD sampling. Water was sampled according to each team requests. Here are examples of usual depths collected by them.

- *Nutrients* (Team 7; PI: Jean-Éric Tremblay): salinity of 33.1, 10, 20, 30, 40, 50, 60, 80, 100, 120, 140, 160, 180, 200, 250, 300 and every 100 m up to the bottom.
- *DIC* (Team 6; PI: Lisa Miller): salinity of 33.1, 10, 20, 30, 40, 50, 60, 80, 100, 120, 140, 160, 180, 200, 250, 300 and every 100 m up to the bottom.
- *Contaminants* (Team 8; PI: Gary Stern): 10, 25, 50, 100, 200 m and bottom.
- *DNA* (Team 7; PI: Connie Lovejoy):
- *Microbes* (Team 7; PIs: Carlos Pedros and Roxanne Maranger):
- *Nepheloid* (Team 7; PI: Jody Deming): bottom and/or nepheloid layer
- *pH/alkanilities* (Team 6; PI: Alfonso Mucci): salinity of 33.1, 10, 20, 30, 40, 50, 60, 80, 100, 120, 140, 160, 180, 200, 250, 300 and every 100 m up to the bottom.

Sampling field

We focused on the Amundsen Gulf southwest of Banks Island.

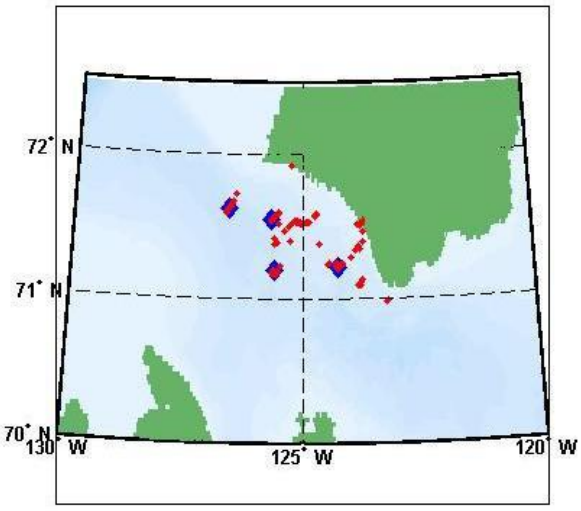

Fig. 1. Positions of Rosette casts shown as red dots; stations of 14 or 15-hour sampling periods indicted by blue diamonds.

Probe calibrations

Salinity: Samples were taken on many casts with small bottles of 200 mL. They were analysed with an autosal GuildLine, model 8400B. Its range spans 0.005 to 42 and its accuracy is < 0.002. The

results were satisfying. The difference between the salinity probe recordings and the samples was around 0.033.

pH: Tests were done twice using two buffers. The sensor is quite stable. Results are as follow:
Buffer 4.01 gave 3.9;
Buffer 7.00 gave 7.32.
Seawater is usually around pH 8; we can expect pH data to be a little over estimated.

Oxygen: Oxygen sensor calibration was performed using Winkler's method and a Mettler Toledo titration machine. Reagent blanks were performed twice; results show that chemicals are still good (m < 4). We sampled oxygen on eight casts. Each time, we choose five depths of different oxygen concentration and sampled three times. Until we changed the oxygen sensor between casts 073 and 074, the results were proportional, thougth not in the same range (m ≈ 0.6). A correction will need to be done on data. After the sensor had been changed, the results were very good; the probe recordings and the samples were always very similar.

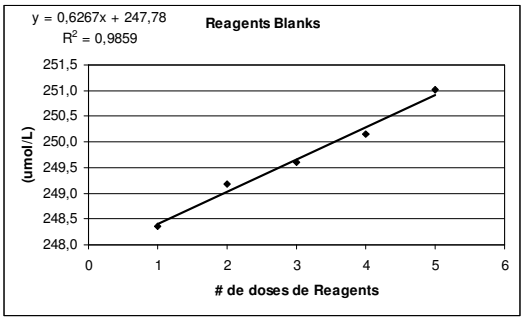

Fig. 2. Reagents blanks (m = 0.6267).

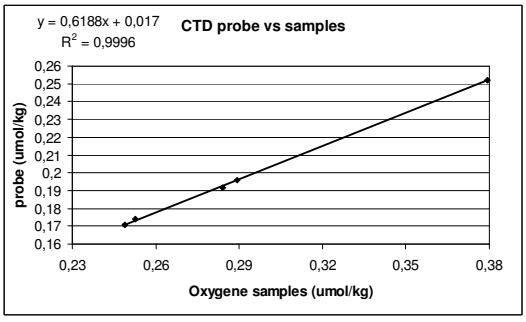

Fig. 3. Relation between samples and probe recordings during cast #045 (m = 0.62).

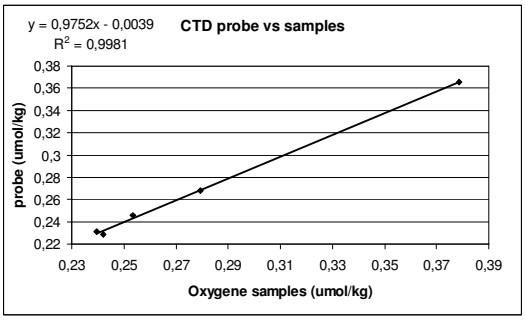

Fig. 4. Relation between samples and probe recordings during cast #074 (m = 0.98).

Problems

- **Sensors**

The oxygen sensor had a huge offset on casts 001 to 073. After that, the sensor was changed and worked properly. The nitrate sensor also had some problems. Thus, nitrate data from casts 134 to 138 are not valid.

- **Bottles**
  Some bottles leaked, a problem that has persisted for several legs. Bottle number 5 did not close all the time.
- **Deck material (winch, A-frame, etc.)**
  The cable guides broke a few times, which is also a recurring problem. The winch functioned without problems.
- **ADCP:** The currents were only partly measured during the last week of the leg. The ADCP could not determine the middle range of the water column currents for a reason that remains unknown. The ADCP also stopped receiving proper information on a few occasions due to ice under the ship.

Available data

All information concerning the Rosette casts are summarized in the CTD Logbook. It includes cast and station numbers, date and time of sampling in UTC, latitude and longitude, bottom and cast depth, comments concerning the cast and its name. A Rosette sheet was also created for every single cast. It includes the same information as the CTD Logbook plus the bottle distribution among every sampling team. The weather information is written in every Rosette Log as well as in a meteorological logbook. For every cast, data recorded at the moment of bottle closure were averaged and recorded in the so-called 'bottle files'. Averaged data are those recorded between 3 seconds before bottle closure and 7 seconds after it. They include the bottle position, time and date, pressure, temperature, salinity, transmissivity, chlorophyll, oxygen, irradiance and pH measurements. All those files are available on the 'Shares'.

- Rosette sheets and the CTD logbook : Shares\Leg5\Rosette\logs
- Bottles files : Shares\Leg5\Rosette\btl
- Plots of every cast including salinity, temperature, oxygen, transmissometer, nutrients, fluorometer and irradiance : Shares\Leg5\Rosette\plots

Between December 20th, 2007, and January 31st, 2008, 158 casts were performed.

Preliminary Results

The 14-hour marathons were performed on four different locations: stations 2007-12D, 2008-14D, 2008-17D and 2008-19D.

Fig. 5. Temperature and salinity data recorded during the 140-hour sampling period on station 2007-12D.

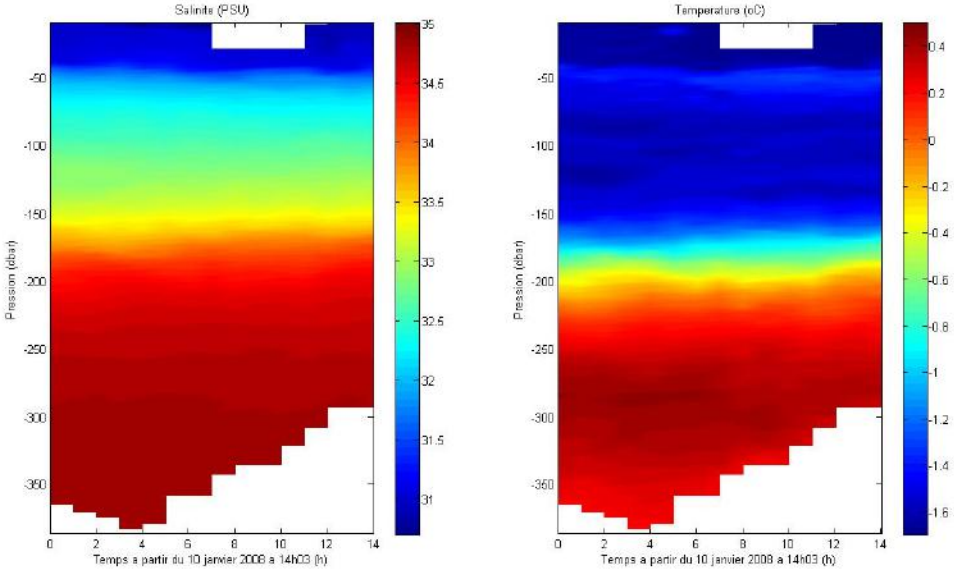

Fig. 7. Temperature and salinity data recorded during the 15-hour sampling period on station 2008-17D.

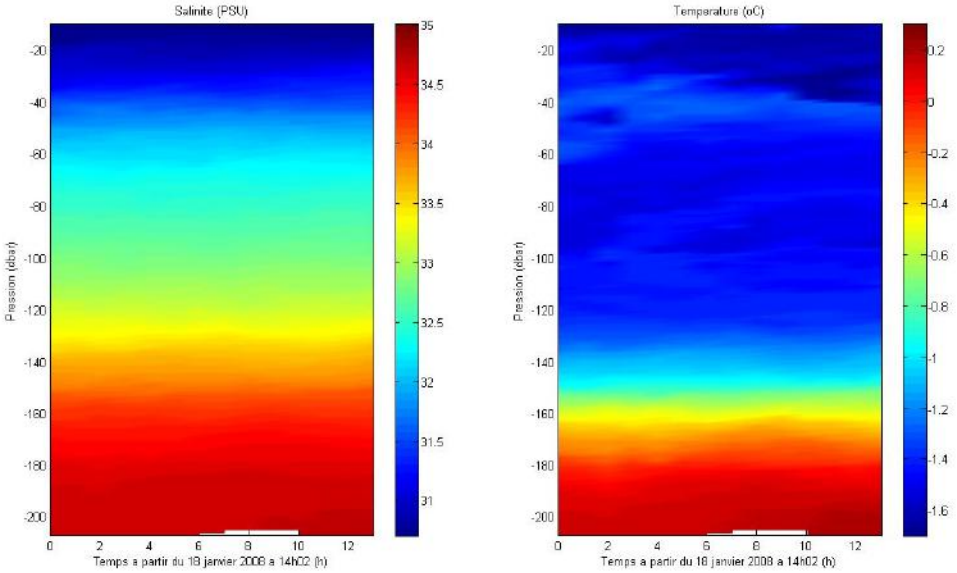

Fig. 8. Temperature, salinity and oxygen data recorded during the 14-hour sampling period on station 2008-19D.

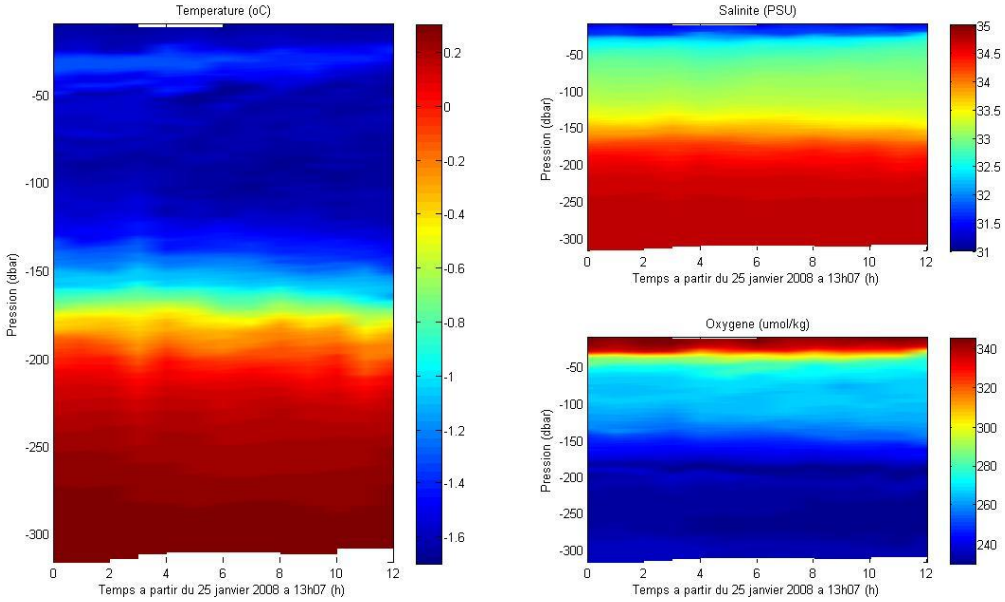

2.1.2. Turbulence

PIs: Yves Gratton[1], Peter Galbraith[2], Daniel Bourgault[3] & Rick Marsden[4]
Participant: Graig Sutherland[3] (gsutherland@mun.ca)

1. Centre Eau, Terre et Environnement Institut National de la Recherche Scientifique, Université du Québec 490 de la Couronne, Québec (Qc) G1K 9A9 CANADA
2. Institut Maurice-Lamontagne Pêches et Océans Canada, 850, route de la Mer Mont-Joli (Québec) CANADA G5H 3Z4

3. Memorial University of Newfoundland, St-John's, CANADA NLA1B 3X7
4. Royal Military College of Canada, Kingston (Ontario) CANADA K7K 7B4

Introduction and objectives

Ocean turbulence acts to mix water properties, such as heat, salt, nutrients, pollutants, etc. In order to understand and predict the evolution of ocean properties at all time scales, from weather to climate time scale, we need to understand how these constituents get mixed given the background (e.g. stratification) and forcing conditions (winds, tides). The objective is to collect *in situ* measurements to quantify ocean mixing in the Beaufort Sea and Amundsen Gulf.

Methods

Turbulence acts first on the velocity field: the propagating waves create line vortices which continuously advect towards each other in complex ways. As those complex structures are relatively stable, the mixing mainly occurs in a region of intense strain created between nearby vortices. The large velocity gradients at small scales (1 mm to 1 cm) can be detected by an air-foil shear probe, a piezo-ceramic bender that generates an electrical charge in response to cross-axial forces. The signal collected by this probe (u') and the deduced shear (du'/dz) can be used to estimated the rate of kinetic energy loss under turbulent event ($\varepsilon \propto (\partial u'/\partial z)^2$, Wkg^{-1} or m^2s^{-3}). A *Vertical Microstructure Profiler* (VMP) equipped with two similar probes has been used in this CFL cruise to sample the turbulent vector field in open water. The VMP free-falls at around 0.6 ms^{-1} and has a sampling rate of 512 Hz, which allows it to measure at the millimetre scale. It is also equipped with a conventional Sea-Bird CTD (*Conductivity, Temperature and Depth* sensor, sampling rate: 64 Hz), two fast response thermistors , and a fast response conductivity probe. The fast response probes also sample at a rate of 512 Hz.

As the vortices are created, the scalars fields (i.e. temperature) are compressed by the strain create between the turbulent structures of the flow. The scalar variance is then driven to smaller scales via eddies as the energy cascade goes on. As soon as they are formed, these thermal anomalies blend into the background by molecular diffusivity at a rate χ, the rate of thermal variance loss ($°C^{-2}s^{-1}$), and this occurs at the far end of turbulence spectrum with the smallest physical scale of overturns. This turbulent mark can be detected by the *Self-Contained Autonomous Profiler* (SCAMP), which is designed to directly estimate the thermal variance produced by diapycnal mixing (which is the mixing across surfaces of constant density). This instrument has two fast response thermistors to measure the temperature gradient at every 0.01 s. As it falls at a rate of 0.1 ms^{-1}, the resulting precision is of 1 mm, which is sufficient to resolve the complete scalar spectrum and to estimate $\chi \propto (\partial T'/\partial z)^2$. The SCAMP is also fitted with PAR, accurate T, accurate C, pressure and fluorometer sensors.

A 600 kHz Acoustic Doppler Current Profiler was set up to measure the water currents directly below the ice surface. A small hole in the ice (~ 40 cm in diameter) is necessary to deploy the current profiler. The profiler is rigidly mounted to the ice in order to obtain turbulence measurements of the underlying current. This was performed as a trial experiment at the last station of this leg; at this time it is uncertain whether the ADCP will be used in this manner on the following legs.

Sampling stations and data management

There were 42 good VMP profiles collected during Leg 5 between December 25, 2007 and January 3, 2008. All of the information relative to each profile, such as position, depth, number of profiles collected, atmospheric conditions, etc., is logged into the Excel file: **LogBook_CFL_Leg5.xls**

There are additional data up until January 17, 2008, but these have numerous bad signals in them due to a bad connection. There are portions of profiles which may be salvageable, but there are no complete profiles after January 3, 2008. Refer to the file **LogBook_CFL_Leg5.xls** for more details on the list of problems with the VMP and the data recorded.

All data are stored on the VMP laptop and a backup copy is stored on G. Sutherland's personal laptop.

The table below summarizes the successful sampling carried out during Leg 5:

Date and Time (UTC)	Lat (N)	Lon (E)
Dec. 26, 2007, 14:46	71º 13.0’	-125º 26.1’
Dec. 27, 2007, 15:20	71º 12.9’	-124º 28.8’
Dec. 28, 2007, 3:42	71º 14.9’	-124º 35.0’
Dec. 28, 2007, 14:32	71º 17.6’	-124º 44.6’
Dec. 29, 2007, 2:18	71º 20.9’	-124º 55.4’
Dec. 29, 2007, 15:00	71º 22.7’	-125º 3.2’
Dec. 30, 2007, 2:20	71º 23.5’	-125º 7.9’
Jan. 1, 2008, 21:25	70º 58.8’	-123º 30.9’
Jan. 2, 2008, 2:34	70º 59.2’	-123º 30.9’
Jan. 3, 2008, 21:25	71º 14.0’	-124º 27.7’

Observations

Figure 1 is an example of a typical profile of temperature, salinity, and microstructure shear obtained with the VMP. The surface layer is well mixed to the halocline, the depth of constant salinity shown here at 40 m, which ranges between 30 and 80 m depth. After that the water column is mostly stably stratified with some variability in the temperature profile. The shear is predominantly low and varies little with depth. More detailed analyses are required to infer turbulent quantities from these measurements.

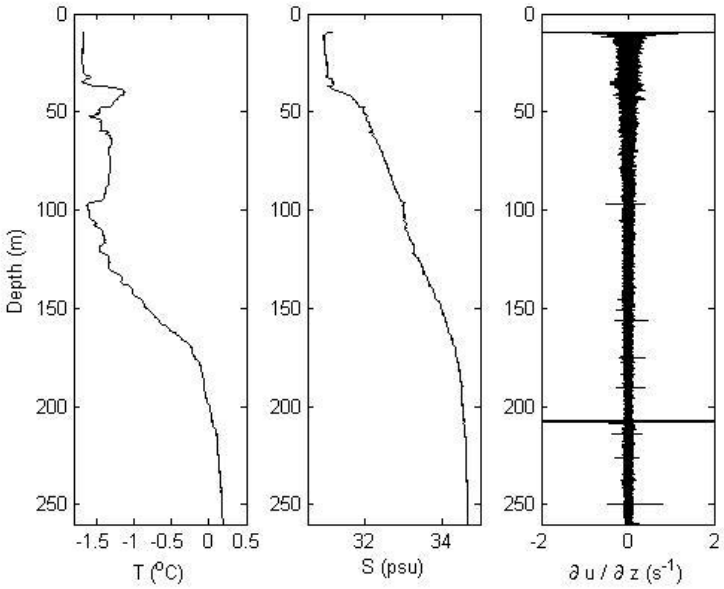

Figure 1: Example of raw temperature, salinity and micro-shear profiles obtained with the VMP on December 26, 2007.

Problems

One of the fast temperature probe channels (channel T2) did not work at all during the entire leg of the cruise. The VMP only obtained measurements for the first two weeks (until Jan 2008) until multiple errors began to appear in the data. Attempts were made to repair the VMP, but the repairs were beyond the scope of what was possible to achieve aboard the ship, so it will be shipped back to the company at the end of this leg. The VMP will be unavailable for the duration of the CFL project.

The SCAMP was not used on this leg as it required a new connector to function properly. This is being brought up for Leg 6 by Peter Galbraith and the SCAMP should be available for Leg 6.

2.2. Team 2

2.2.1. Ice dynamics

PI: David Barber
Participants: Monika Pucko, Mukesh Gupta, Dustin Isleifson, Andre April, Charles Hannah

General Ice Conditions
Throughout Leg 5 we mostly encountered large floes of first year ice, as expected for the drift portion of the CFL project. Towards the end of the leg we began to see snow accumulation with drifts up to ~35 cm. There were several opportunistic visits of other forms of ice, including newly forming sea ice in Leg 5B. Via helicopter we visited several multiyear ice floes for beacon deployment and on ice reconnaissance missions. An ice thickness camera system was operated during transit from the port side of the ship in order to observe the various ice thicknesses.

Physical Sampling
A standardized sampling program was implemented at the beginning of Leg 5, with further refinements in the sampling strategy appearing in Leg 5B. The goal is to obtain physical and microstructure measurements of the snow and sea ice. We were able to visit the site regularly via the gangplank on the ship. During the drift mode of the project it is imperative to set up a fence around the EM measurement location and have all crew informed of the need to respect the area, such that it would not be accidentally disturbed.

Our standard sampling plan includes measurements of snow and sea ice geophysical parameters. A weekly schedule was set up which included visiting the ice twice daily in order to develop some statistics on the snow and ice profiles. First, the ice surface condition was recorded and site photos were taken. Each visit included a full snow pit measurement including temperature profiles, salinity profiles, capacitance plate measurements, density measurements, and snow grain photos. Two ice cores were taken at each visit to obtain the temperature and salinity profiles. At each site the vertical microstructure and sometimes the horizontal microstructure was studied. Furthermore, ice core density profiles were regularly obtained.

The cold lab temperature was regularly maintained throughout Leg 5, even with a high frequency of use. The system goes through a defrost cycle daily and this worked to maintain the temperature at an appropriate value. Again, we found that it was useful to have a day every so often during which the cold lab was heated in order to defrost the condenser on the cooling unit. This is to maintain regular temperatures in the laboratory.

Six different sites were visited throughout Leg 5. Since we were in the drift mode stations we visited the ice each day to observe the diurnal variability, with the exception of Station 2008D18B since it was an ice raid implemented during transit between stations. The ice stations that were sampled are summarized in Table 1.

Table 1: Ice station sampling summary.

DATE	STATION	SNOW	ICE TYPE	ICE MICRO
25-Dec-07	2007D11	2 cm	First year ice (30.5 cm)	Vertical

Ship Based EM Measurements

EM measurements were conducted throughout Leg 5 in order to observe the interaction of electromagnetic radiation with various ice conditions. The collected data will be used in electromagnetic modeling studies and for calibration of satellite remote sensing data. The results of this study will allow for us to improve our knowledge of the temporal evolution of sea ice physical, thermodynamic, and electrical properties.

Scatterometer

A fully polarimetric scatterometer system was operated twice daily at each station. The system was mounted at a height of 8.2 m above the surface. Measurements from the ship were conducted with a sweep from -30° to 30° in the azimuth, requiring the 0° reference at a perpendicular line to the ship's side. The variation in elevation was measured with sweeps in the elevation at 5° increments on the range 20° to 60°. An infrared transducer (Everest, 4000L) was mounted on a rail near the scatterometer.

Upon arrival at Station 2008D19, we had issues with breaking too much ice in the field of view of radar. Even with several careful attempts the ice was turned up and/or flooded. We managed to reach a site with minimal breakage, but after one day we had to reposition the ship in order to clear out the moonpool. This resulted in the area becoming splashed with seawater and therefore unusable. With this, an interesting opportunity arose to place the scatterometer at a height of 13.5 m on the starboard side of the ship for a single day experiment. The scatterometer was successfully positioned and the scan region was thoroughly sampled. The device is currently located once again in its regular position on the port side in the scatterometer shed.

Fig. 1. Scatterometer mounted on the starboard side of the ship and overlooking the sample area that was previously marked out using flags.

At the beginning of Leg 5B, we noticed that sometimes the noise floor of the system rises and therefore some of the radar returns are lost in the noise and corrupted. The source of this problem has not yet been determined, but the data is still usable if in the final analysis the corrupted data points are removed.

Ship-Based Radiometer (SBR)
Dual polarized radiometers operating at 37 GHz and 89 GHz with a 6° were mounted about 13 m above the sea surface on the port side of the ship. During transect operation the radiometers were kept at an incident angle of 55°. Concomitant with the scatterometer operation, scans were performed, changing the incident angle from 30° to 150° using 5° steps. A network camera was used to monitor the surface conditions at a sampling rate of 10 s. The settings have not been changed otherwise. In addition, a hand-held camera is used at each site to provide more information on the surface conditions.

Ground Penetrating Radar
A ground penetrating radar system (GPR) was used to investigate snow and sea ice thickness and structure on an opportunistic basis. Due to time constrictions only the 1 GHz unit was used. Several interesting datasets were collected simply using stationary measurements, or small transects over ice cracks. We are currently awaiting the return of the odometer unit in order to provide better control of our data collection process in transect operations.

Atmospheric Sampling Program
The purpose of the atmospheric sampling program is to monitor cloud cover and cloud properties, upper level and boundary layer winds, temperature, and humidity. In general, there were no major problems to report with this aspect of our sampling program.

All-Sky Camera
The all-sky camera system is used to take pictures of sky in order that percentage and type of cloud cover may be determined throughout the cruise. Due to breakage of the reflecting dome, the system is not currently in operation.

Ceilometer
The ceilometer is used to measure the height of the cloud layers above the ship. The ceilometer was fully functional throughout all of Leg 5. Routine maintenance and backup was performed at regular intervals.

Profiling Radiometer
The profiling radiometer is used to measure the temperature, relative humidity, and pressure within the atmosphere. It was activated in Leg 4 and has been running continuously through Leg 5.

Laser Precipitation Gauge
This instrument was fully functional throughout Leg 5. The instrument continues to run, and all data has been downloaded and archived.

Ice Motion Beacons
We were able to deploy a total of four ice beacons during Leg 5. During this time we lost the one beacon that had intentionally been deployed on first-year ice, along with two others on multi-year ice in a linear geographical fashion near 2008D17 to assist with navigational issues and selection of the next drift floe.

Table 2: Ice motion beacon deployments.

Beacon ID	Date Deployed	Location Deployed	Status
25330	January 6, 2008	2008D14	ACTIVE
915930	January 15, 2008	FYI near 2008D17	LOST
917920	January 15, 2008	MYI near 2008D17	ACTIVE
20600	January 15, 2008	MYI near 2008D17	ACTIVE

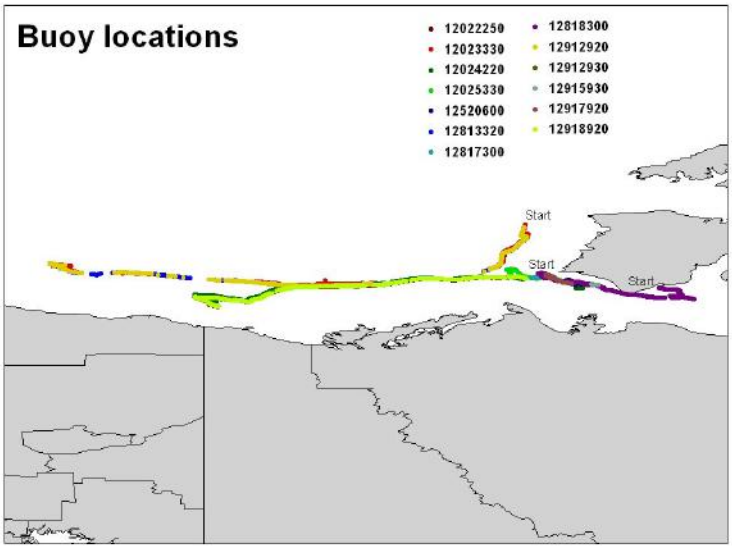

Fig. 2. Ice beacon locations as of January 28, 2008.

AVOS (Environment Canada MetObs System)
The data from the AVOS has continued to be regularly collected and monitored by our group throughout Leg 5 as part of our sampling plan.

Recommendations
The greatest challenge that we faced in Leg 5 was arriving in a site while not damaging the ice near the ship. Whereas before, when the ice was thinner, it was feasible to try several times and eventually succeed, it seems that during this part of the year it is nearly impossible to obtain an ideal EM site. The key aspect to avoid is the splashing of seawater on the surface since it will completely change the characteristics, as well as minimizing large cracks and overturned ice within 2 m of the ship. While nearly impossible to attain, with the care and skill in navigation that the crew of the *Amundsen* has demonstrated, a reasonable compromise can always be reached.

2.2.2. Satellite Imaging of the Ice Field

PI: Dave Barber
Participant: André April, Ph.D
Previsionniste des Glaces/Ice forecaster
Environnement Canada, Environment Canada
Ottawa
April.Andre@ec.gc.ca

I received by ftp 42 Radarsat and Envisat images to compare with 8 Palsar images (Japanese imagery). The first conclusion is that Palsar is very sensitive to roughness; telling the difference between thin ices and leads is difficult. But, this can be a plus for navigational purposes, because the dark black tones of thin ice and leads, which indicate navigable passages, are easy to detect. Ridges are easily identified on Palsar by their very bright white tone, mainly when they are higher than 6 feet. Old ice as multi-year ices are better seen on Radarsat, mainly because their rounded ridges are not reflective on Palsar images. Flat floes with the same average thickness are easily seen on Palsar images, better than on Radarsat or Envisat images, by the fact of their similar grey tones. Overall, it was possible to obtain a good understanding of winter arctic sea ice from the Palsar images. The next related effort must be in spring or autumn, when thinner ice is present, in order to focus on the signals reflected by this thin ice. Thank-you for everything, merci, pour tout -- it was for me a great experience.

Note added by Chief Scientist: In addition to his own work, Andre joined reconnaissance flights and assisted with evaluations of floe thickness. He also assisted with on-ice operations from the ship, helping other team 2 members with their projects, for which we are grateful.

2.2.3. Heat Fluxes and Ice Growth

Transformation of Air Masses and the Energy-Exchange Processes between the Ocean and Atmosphere in the Flaw Lead Area

PIs: Alexander Makshtas, Sergey Shutilin, Peter Bogorodsky
Participants: Sergey Shutilin, Peter Bogorodsky, Mikhail Makhotin

Background
Flaw leads are the centers of powerful energy exchange between ocean and atmosphere during the winter period. They have sizeable input to ice mass balance due to growth of young sea ice. Steep vertical and spatial gradients in temperature and humidity exist over the ice and water along with different atmospheric boundary layer stratifications over both of these surfaces. Vertical profiles of the primary atmospheric characteristics and stratification within the air mass move the ice edge, dividing the water in the lead from the surrounding ice. As a result the heat fluxes should change depending on distance from the edge, wind speed and direction, and values of initial temperature and humidity. They should be reflected in changes in ice growth rate. Mechanisms of ice cover structure formation in this area are closely connected to the processes of the atmospheric boundary layer transformation and the changes of the aerodynamic characteristics on the border between the ice and open water. These processes of air mass transformation can be reproduced by a combination of atmospheric and ice models, but to improve such models requires detailed study of the transformation processes in the atmospheric and ocean boundary layers and the features of the energy exchange at both interfaces near the border of fast ice and flaws.

Field work plan for Leg 5
Plans called for executing this complex work shipboard and on the ice at various distances between the points of measurements, depending on the different wind speed and direction relatively to the ice edge. Several multi-day series of profile and heat flux measurements should be accomplished, depending on weather conditions. Desired field observations consist of:
1. Measurements of air temperature and humidity, wind speed and direction within the surface atmospheric boundary layer carried out at two or three levels by using the sensors mounted on a mast or tower. The tower should be installed on the ice surface near to the open water in a lead or polynya itself;
2. Measurements in detailed profiles for all mentioned characteristics from the surface up to 1000-2000 meters height performed by sensors installed on a balloon. These profile measurements can be realized in parallel (synchronously) on the ice and shipboard.
3. Short- and long-wave radiation balance should also be measured on the ice and shipboard;
4. Direct measurements of the heat and moisture fluxes by the high frequency sensors for turbulent measurements;
5. Measurements of disturbances of water temperature and current velocity beneath ice bottom; and
6. Heat fluxes and ice growth rate calculation based on standard meteorological data and comparison to the direct measurements.

Meteorological and heat flux measurements
Meteorological information was collected from several different sources during the Leg. First, a wind sensor was installed on the front mast of the ship at a height of about 30 m, along with temperature and humidity sensors at bridge level at a height of about 15m. ***AVOS (Environment Canada MetObs System)*** with additional wind sensor at the top of the bridge provided information about the position of icebreaker, relative and true wind speed and direction, air and sea surface temperatures, relative humidity, ship's heading and speed.

A heat flux tower was installed in addition on the front deck and collected data about atmospheric pressure, air and sea surface temperatures at 18 m height, relative humidity, wind speed and direction for each minute during all time of the Leg (Fig.1).

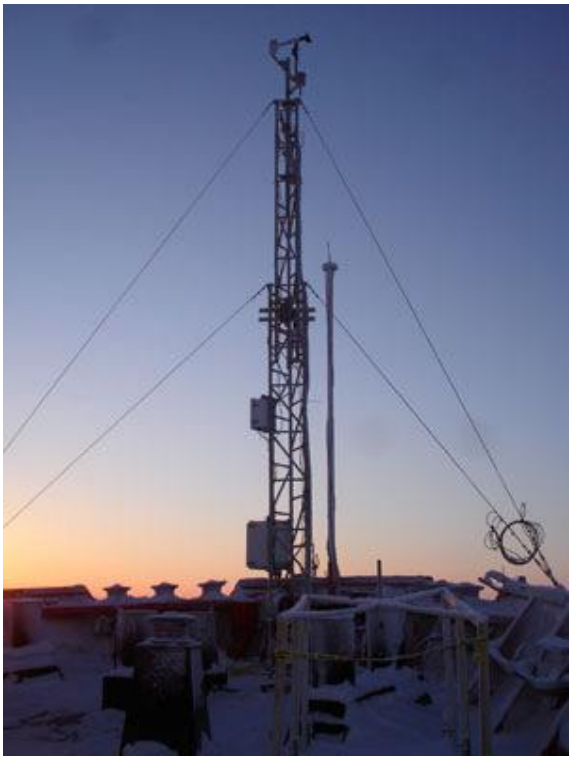

Fig.1. Meteorological tower installed at the front deck.

A heat flux tower and additional meteorological mast was installed for the first time during the Leg on January 9. It had been impossible do so earlier due maneuvers of the ship within compact ice cover and absence of enough open water in the neighborhood. The mast was deployed on the drifting ice floe at a distance of 300 meters from the lead and, at approximately the same distance, sensors were installed on the tower. First long-term measurements on the ice started 3:30 GMT on January 10 and continued until 14:25 GMT on January 11 (Fig. 2).

Fig. 2. Meteorological mast and heat flux tower at the ice station.

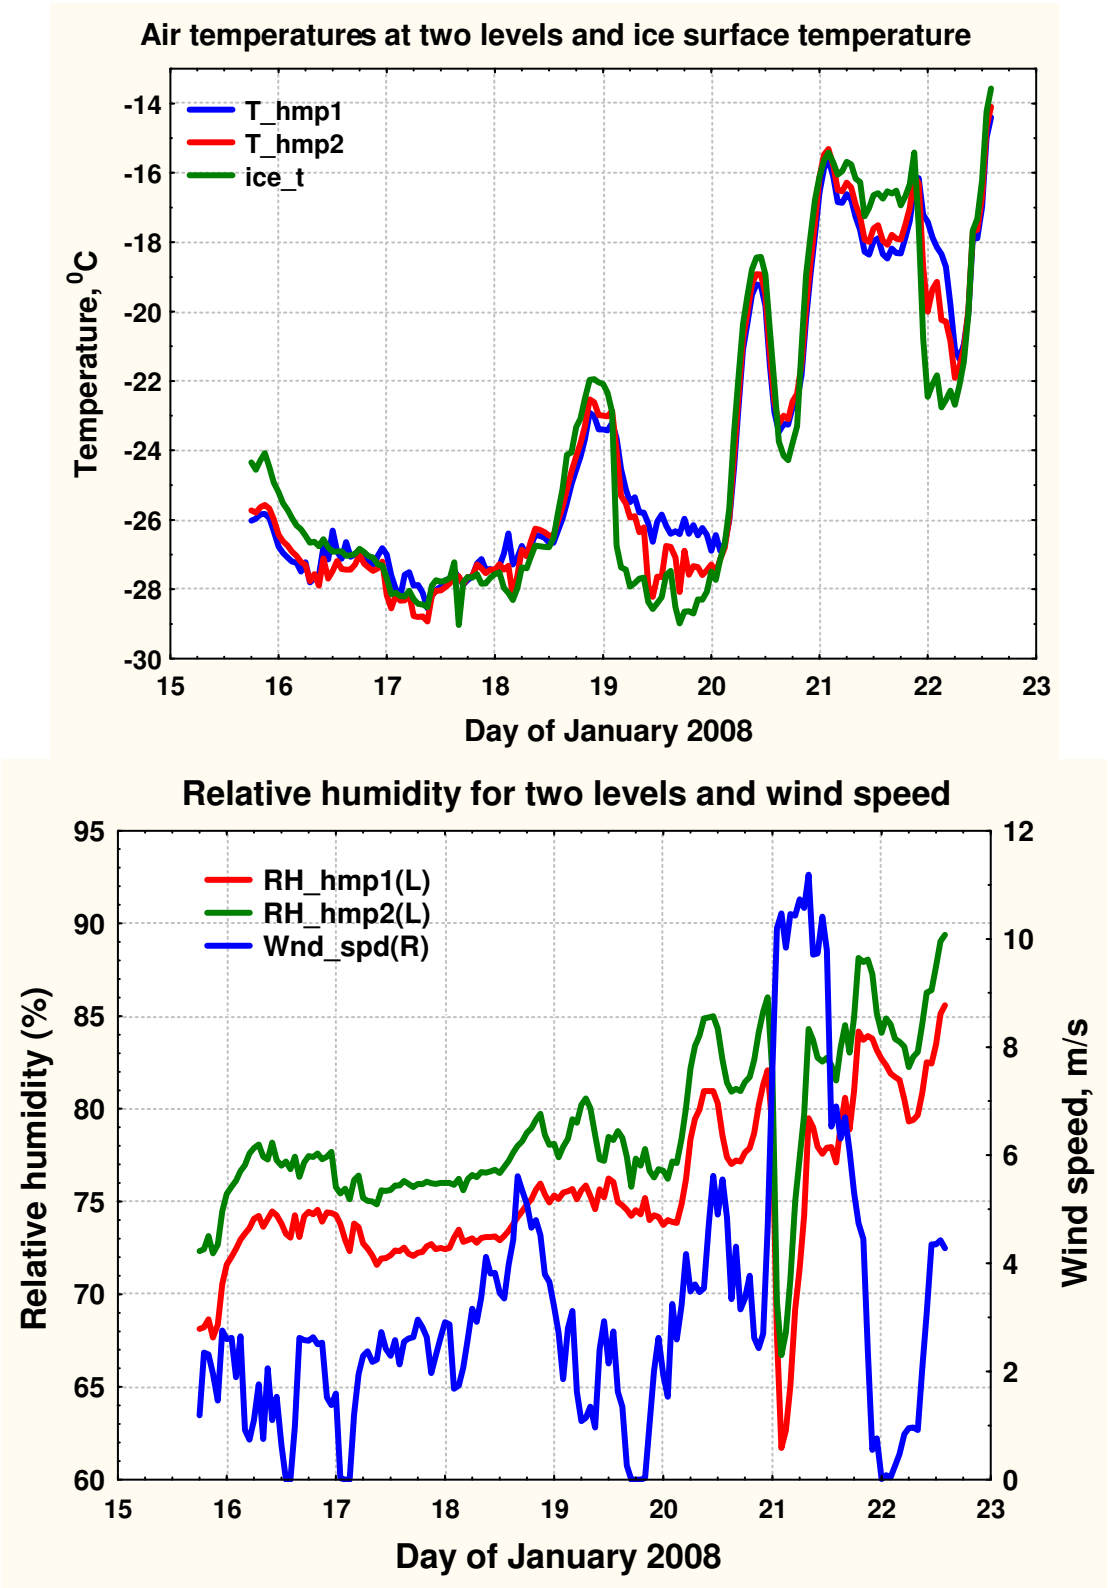

Fig. 3. Temporal variability at two different levels of air temperature and ice surface temperature (a), along with two levels of relative humidity and wind speed (b) from the meteorological tower installed on the ice.

The second part of the Leg was more successful for this part of the program. The next ice station began soon and the heat tower and meteorological mast were installed again on January 15. They remained in operation until January 22, when the ship had to relocate. For the last time, the ice mast

and tower were deployed on ice on January 25 and measurements continued until the end of Leg 5 on January 30. In total, the period of almost continuous measurements on the ice was 12 days during Leg 5. As an example, temporal variability of air temperatures and relative humidity at two levels along with ice surface temperature and wind speed, measured at the ice in period from January 15 to January 23 are shown in Fig.3. The vertical turbulent fluxes of sensible and latent heat were calculated, based on data of these measurements (Fig. 4).

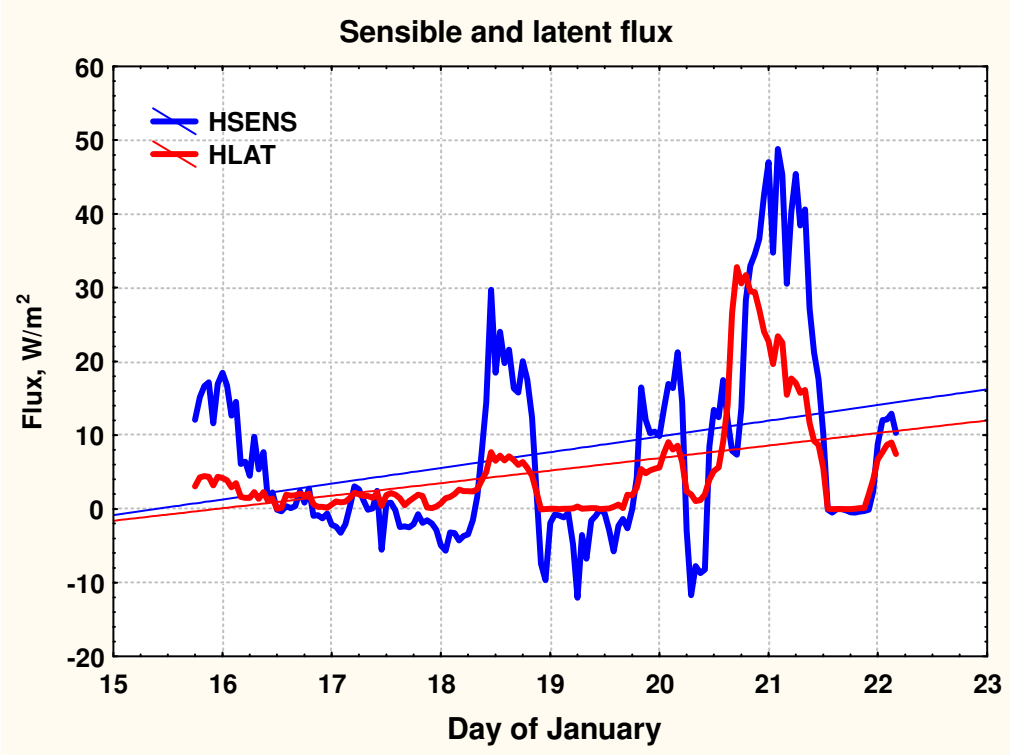

Fig. 4. Sensible and latent heat fluxes calculated from meteorological mast data.

Preliminary analysis of the Fig. 3 and Fig. 4 demonstrates that weather conditions during this ice station were unstable. Calm conditions were replaced by moderate winds and back again. Temperature variations reached values of 14^0C. As a result, essential variations in sensible heat flux values occurred. Even this flux changed direction from ice to atmosphere and back.

Ice cores were taken daily in the neighborhood of the mast position to determine the ice and snow thickness, along with temperature and salinity profile measurements within the ice. These measurements should provide the information to compare temperature distribution within the ice and ice growth rate simulated by the ice model with observational data.

Because the specially equipped balloon, designed to carry out the measurements of fine structure of the surface atmospheric boundary layer was unavailable, we attempted to use the standard block of sensors for ***Radiosondes (weather balloons)***. This block provides information about vertical distribution of the air temperature, humidity and atmospheric pressure, along with DigiCora System data for wind calculation based on GPS position of the ship and balloon. The tethering of balloons was carried out daily from the tent near to the starboard side of the *Amundsen* using a winch and fishing-line (Fig. 5). In total, we accomplished nine launchings of the balloon (Table 1) up to several hundred meters. A few attempts failed due strong wind. Maximal height of the balloon rising depended on wind speed and weather conditions. In addition, one full-scale launch of balloon was completed at the end of Leg 5. All data from the successful launches were stored in Climate archive on the *Amundsen* server. The weakness of this method is calm weather or wind speeds of less then 5 m/s during the launch, because speed of the line release cannot be higher than this value. Meanwhile, wind data received during the same procedure can be used as an estimation only, because the line itself placed

limitations of the degree of freedom of the balloon. A better approach would be to use a less filled balloon or add height to address the balloon's rise and speed. Using the special balloon described earlier with independent wind sensors can resolve this problem.

Fig. 5. Performing of the balloon launch.

Meanwhile, several events of vertical temperature inversion were detected by the launches. These inversions were driven by different reasons. In the first case, the inversion was produced by cooling of the surface boundary layer of atmosphere due to the contact with colder ice surface. In the second, advection of relatively warm and wet air masses from open water over the dry and cold ice surface caused the inversion.

Table 1. Dates, places and maximal height of balloon launches from CCGS *Amundsen*.

N	Date	Coordinate		Max height
		Lat, N	Lon, W	
1	17.01.08	71.31 N	124.58 W	506
2	18.01.08	71.32 N	124.59 W	152
3	20.01.08	71.34 N	125.03 W	342
4	20.01.08 (2)	71.34 N	125.03 W	459
5	25.01.08	71.11 N	125.06 W	276
6	27.01.08	71.06 N	125.54 W	423
7	28.01.08	71.06 N	125.54 W	459
8	29.01.08	71.06 N	125.54 W	543
9	30.01.08	71.06 N	125.54 W	340

Some examples of the vertical profiles of air temperature, humidity and wind speed were shown at Figure 6. These data will be complemented by data provided by the ***Profiling Radiometer System.*** The profiling radiometer was used to measure the temperature, relative humidity, and pressure within the atmosphere. It was activated fully in the previous Leg since November and stayed in operation up to the end of Leg 5. The instrument has collected data on the standard high pressure inversions that are characteristic of this region, as well as boundary layer temperature and humidity profiles up to 10,000 meters.

Additional information

Additional information about turbulence beneath the ice bottom or current perturbation is important for correct calculation of ice growth rate and estimations of the heat flux through the snow-ice cover. Unfortunately, this information about turbulence for upper 10 m of water layer beneath the ice was unavailable, because standard ship ADCP is mounted at that depth, while the portable sensor for work from sea ice was inoperable.

Total cloudiness data are very important for correct calculation of long-wave radiation balance. This information should be available from ***All-Sky Camera device.*** The all-sky camera system is used to take pictures of sky in order that percentage and type of cloud cover may be determined throughout the cruise. The all-sky camera is now fully functional, and requires daily maintenance to ensure the dome is not frosty. The all-sky camera became non-functional during the Leg 5, due damage of sky-doom plastic cover.

Useful information about surface temperature is provided by the ***Ship-Based Radiometer (SBR).*** Dual polarized radiometers are mounted about 12 m above the sea surface on the port side of the ship. During transect operations the radiometers were kept at an incident angle of 55°. At station stops the system was operated in a scan mode, changing the incident angle from 30° to 150° using 5° steps. A network camera was used to monitor the surface conditions at a sampling rate of 10 s. The settings

have not been changed otherwise. In addition, a hand-held camera is used at each site to provide more information on the surface conditions.

Ice growth simulation

Detailed investigation of sea ice evolution can be performed using a variant of mushy (skeletal) zone classical model (see, among others, Ref. [1]), which describes the simultaneous sea ice growth and its surface heat budget depending on seawater initial temperature and salinity, and changing atmospheric conditions, the air temperature and humidity, the atmospheric pressure, the wind velocity, cloudiness and the snow accumulation. The one-dimensional, thermodynamic, nonlinear model is based on heat and mass transfer equations and boundary conditions imposed at the upper and lower unknown moving interfaces of mushy zone (Ref. [2]) and taking into account heat fluxes at the air-ice surface. Figures 7 and 8 demonstrate a scheme of the process and the model equations (the temperature field in the mushy zone is described by equations (1a), relationship (1b) describe the salinity field in form of Scheil equation and accordance with linear liquidus slope (1c), expressions (2) and (3) represent the heat and mass fluxes imposed at the phase transitions interfaces). As an example the calculations for two variants of sea ice growth differs by initial depth by the same variations of atmospheric conditions measured on meteorological tower in 15-22 January 2008 (see Fig. 3) is performed.

Initial thickness of ice in first variant was equal to the ice floe thickness at the place of tower deployment. The second variant corresponds to open water (lead). The information of seawater temperature and salinity was taken from the Ref. [3]. Figures 9a,b-12a,b shows model results for sea ice thickness, growth rate, interface temperatures and components of ice cover surface heat budget during 15-22 January 2008 for first (a) and second (b) variants at atmospheric and ocean heat fluxes parametrization found in Refs. [4,5]. The results obtained are in good agreement with experimental data (Figure 13). In particular, the growth of sea ice is not simple a square-root function of time. Further accumulation of meteorological information will allow analyzing sea ice thermodynamic evolution in the studied region from formation up to disappearance and also estimating variation of air-sea energy exchange parameters.

Governing Equations for the Mush

$$T_m(z,t)=\frac{T_2-T_1(t)}{h_m(t)-h_i(t)}\left(z-h_i(t)\right)+T_1(t)\,,\quad f_w\frac{\partial S_m}{\partial t}=-S_m\frac{\partial f_w}{\partial t}\,,\quad T_m(z,t)=-\gamma S_m(z,t)\,,\qquad h_i(t)\le z\le h_m(t)$$

(1a,b,c)

Boundary Conditions

$$\rho_i L f_{w1}\frac{dh_i}{dt}=k_i\frac{\partial T^-}{\partial z}-\left(k_i\left(1-f_{w1}\right)+k_w f_{w1}\right)\frac{\partial T^+}{\partial z}\,,\quad S^+\frac{dh_i}{dt}=-D f_{w1}\frac{\partial S^+}{\partial z}\,,\qquad z=h_i(t)$$

(2a,b,c)

$$\rho_i L f_{i2}\frac{dh_m}{dt}=\left(k_i\left(1-f_{w2}\right)+k_w f_{w2}\right)\frac{\partial T^-}{\partial z}+\rho_w C_w\alpha^* u^*\left(T_\infty-T_2\right),\qquad z=h_m(t)$$

(3a,b,c)

T is the temperature, S is the salinity, z is the vertical coordinate, t is the time, f is the local volume fraction, γ is the liquidus slope, h are the positions of interfaces, ρ is the density, L is the latent heat, k is the thermal conductivity coefficient, D is the diffusion coefficient, C is the specific heat, α^* is the turbulent coefficient, u^* is the friction velocity, subscripts "i", "m", "w", "1", "2", "∞" denote the solid zone, mushy zone, seawater (brine), upper and lower boundaries of mushy zone and far-field value, respectively, superscripts "+", "–"denote the upper and lower sides of interfaces, respectively.

2.2.4. Aeolian and Ice Transport of Matter in the Circumpolar Flaw Lead

PI: Vladimir Shevchenko
Participants: Vladimir Shevchenko, senior scientist, e-mail: vshevch@ocean.ru
Natalia Goryunova, PhD student, e-mail: goriounova_natalia@rambler.ru
P.P. Shirshov Institute of Oceanology RAS
36, Nakhimovsky prospect
117997 Moscow, Russia
Tel.: +7-495-1247737, Fax: +7-495-1245983

The aim is to study in detail particulate matter in snow, drifting ice and under-ice water in the areas of circumpolar flaw leads and to estimate their influence on sedimentation and pollution of the Arctic.

During Leg 5 the following studies were done:

Snow research
(composition of dissolved phase; particulate phase, including black carbon)

Snow samples were collected in clean polyethylene bags at a distance > 200 m from the ship upwind or > 150 m from the helicopter upwind. They were melted at room temperature in plastic buckets in a clean container room. Salinity/conductivity and pH were measured when melting was finished. After the snow had melted, the melt water was filtered through pre-weighed nuclear-pore lavsan (polyester) filters (47 mm in diameter, 0.45 µm pore size) and Whatman GF/F filters (47 mm in diameter).

The filtrate from the nuclear-pore filtration is collected for ion analysis (the small 50-ml bottles are stored in the refrigerator) and trace metal analysis (we add 0.5 ml of super pure nitric acid and store them). Filters will be weighed in Moscow to determine the concentration of particulate matter. After that, the elemental composition of particulate matter will be determined by atomic absorption method and scanning electron microscopy will be done (we will try to do it together with X-ray microprobe).

The filtrate from the GF/F filtration is collected for analysis of dissolved organic carbon. Samples are acidified with a few drops of H_3PO_4 and will be analyzed at the University of Manitoba.

GF/F filters will be used for determination of total and black carbon.

We collected 13 snow samples.

Analysis of snow samples could give us information about fluxes of matter from the atmosphere to the drifting ice and about the sources of this matter.

In a few samples of snow, elevated quantities of brownish mineral dust was registered. Detailed study of its composition and calculation of back trajectories of air mass transport may reveal possible source areas. Previously, a few cases of Asian dust and associated pollutant deposition in the Canadian and USA Arctic were reported [Wilkening et al., 2000; Stohl et al., 2002]. The data on the black carbon distribution in snow could be interesting from the Arctic warming point of view [Sharma et al., 2004]. Snow becomes dirty when soot from tailpipes, smoke stacks and forest fires enters the atmosphere and falls to the ground and ice. Dark surfaces absorb sunlight and cause warming, while bright surfaces reflect heat back into space and cause cooling.

Study of ice and under-ice water

Ice sampling consisted of several (3–5) ice cores taken at the same place on the same day. We cut cores into 3–4 subsamples, combined the corresponding pieces and melted them at room temperature.

Under-ice water samples were collected by a 2-l Niskin bottle.

We measured salinity/conductivity and pH in ice-melt and under-ice water, then filtered the water the same way as snow-melt water.

The filtrate after filtrating two cores was collected for trace metal analysis.

On the ice floe D-17 we carried out an *in situ* experiment. On January 15 we took 10 ice cores in the area of thin ice. The average ice thickness was 45 cm. Two sub-samples from these cores were obtained (layers 0–22 cm and 22–45 cm). We drilled at the same place on January 19 (ice thickness was 52 cm) and January 21 (ice thickness was 56 cm). Each time we cut a layer of newly formed ice (deeper then 45 cm). This approach gives us the possibility to study concentration and composition of newly formed ice. With the same goal, we took samples of nilas on the transit from ice floe D-17 to ice floe D-19 on January 23 together with other interested groups.

Our results will be compared with literature data from Siberian flaw leads and the Mackenzie River mouth zone to estimate the role of different source areas in the delivery of sedimentary matter to the Arctic by drifting ice and its role in modern sedimentation.

We collected 21 integrated ice cores and 13 samples of under-ice water.

This work is done within the framework of International Polar Year 2007/2008 project No. 323 "Aeolian and ice transport and fluxes of matter (including ecotoxicants) in the Arctic" included in the OASIS cluster.

2.2.5. Optical Observation

PI: Jinping Zhao
Participants: By Tao Li, Shujiang Li and Xiang Li

Key Lab for Polar Oceanography and Global Ocean Change

Ocean University of China

Objective
The goal of our experiment is to measure the attenuation coefficients of the vertical incident light through sea ice and snow of different thicknesses and to study the lateral scattering of light using an artificial light that has a spectrum of wavelength bands, simulating the Sun.

Materials and methods

Materials
The instruments used for optical observation are a high resolution Profiling Reflectance and Radiometer (PRR) made by Biospherical Instruments Inc. (BSI, USA). The system includes both an underwater profiler PRR-800 and a surface unit PRR-810, which collect signals simultaneously. Both instruments are multispectral units with very high resolution and sensitivity - enough to detect the light in dark conditions under sea ice. The parameters for the system are described below.

The following equipment is needed in the field：

No.	Name of equipment	Weight
1	Fluorescent lamp	20 kg
2	Optical instruments	15 kg
3	Cables + 250W lamp	15 kg
4	Power generator	10 kg
5	Jiffy driller	5 kg
6	Underwater frame	15 kg
7	Computer	2 kg

8	Desk box of optical instruments	4 kg
9	Tripod, ruler, toolbox, spade	3 kg

Fig 2.1. The equipment for the light experiment

Methods

The operations of the experiment for the attenuation coefficient of the sea ice are as follows:

Step	Operation	Note
1	Choose proper experiment field	Avoid stepping on the field
2	Start ice driller and drill a hole on ice	Measure ice thickness
3	Generate electricity	Use a connector with 3 plugs
4	Switch on the lamp	Preheat for about 15 minutes
5	Link and deploy PRR-800	Put in accurate position
6	Put PRR-810 on tripod	
7	Start instrument system	Keep computer warm before using
8	Measure downwellings with snow	
9	Calibrate with snow	
10	Remove snow and measure	Measure snow thickness
11	Calibrate without snow	
12	Finish	

The methods to measure the attenuation coefficient of the lateral scattering light through sea ice are as follows:

Step	Operation	Note
1	Choose proper experiment field	Avoid stepping on the field
2	Clear the snow at the place chosen	In order to move the lamp steadily
3	Drill three holes with depth of 50 cm	The holes do not reach the seawater
4	Generate electricity	Use a connector with 3 plugs

5	Switch on the lamp	Preheat for about 15 minutes
6	Link and deploy PRR-800 and PRR-810	Put in accurate position
7	Move the lamp in the different depths of the holes and record data	The depth of each 10 cm is required
8	Snow sampling for the density of the snow	
9	Finish	

Fig 2.2. The experiment on lateral scattering of the light

The operations of the experiment for the attenuation coefficient of the snow are following as:

Step	Operation	Note
1	Make a snow hill with 2.5m*1.5m*1.2m	
2	Measure snow hill thickness	
3	Generate electricity	Use a connector with 3 plugs
4	Switch on the lamp	Preheat for about 15 minutes
5	Link the equipment	
6	Put the lamp on the side of snow hill	
7	Deploy PRR-810 on the other side	Put in accurate position
8	Record data	
9	Calibrate the light field	Keep computer warm before using
10	Snow sampling for the density of the snow	
11	Clean the snow to the thickness of 10 cm on the side of PRR-810	
12	Repeat steps 7-11 till the thickness of the snow is less 10 cm	
13	Finish	

Fig 2.3. The experiment to measure the attenuation coefficient of the light through snow

The operations of the experiment for the attenuation coefficient of the snow at different depths are as follows:

Step	Operation	Note
1	Choose proper experiment field	Avoid stepping on the field
2	Measure snow thickness	
3	Start ice driller and drill three holes on ice	Measure ice thickness
4	Generate electricity	Use a connector with 3 plugs
5	Switch on the lamp	Preheat for about 15 minutes
6	Link and deploy PRR-800	Put on accurate position
7	Put PRR-810 on tripod	
8	Start instrument system	Keep computer warm before using
9	Measure downwellings with full snow	
10	Calibrate with the snow	
11	Remove some snow to change the thickness of snow	Measure snow thickness and snow sample for density
12	Measure downwellings with that snow	
13	Calibrate with the snow	Repeat steps 11-13 until ice surface is reached
14	Finish	

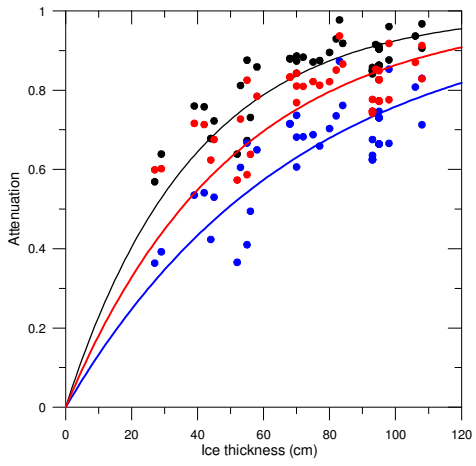
Fig 2.4. The experiment to measure the attenuation coefficient of the light through snow layers of different thicknesses.

The options of the CTD experiment are as follows:

Step	Operation	Note
	Get the water depth from bridge	Before being on the ice
1	Choose proper experiment field	
3	Start ice driller and drill three holes on ice	
4	Turn on the CTD and let it go down slowly	
5	Stay for 1 minute at depth of 60 m, then go up	
6	Turn off	

Results

Results of experiment on vertical attenuation of sea ice



The vertical attentuations of the light in sea ice of different thicknesses are shown in the dark (710 nm), blue (490 nm) and red (410 nm) lines, respectively. The dots are taken from the field experiments, while the lines fit the data to exponential form.

2.3. Team 4

2.3.1. Food web. Zooplankton and fish, Acoustic

PI: Louis Fortier
Participants: Marc Ringuette (U. Laval), Stéphane Thanassekos (U. Laval), Josée Michaud (U. Laval), and Steeve Gagné (electronic technician from U Laval).
Written by: Josée Michaud, Marc Ringuette and Stéphane Thanassekos

THE ZOOPLANKTON SAMPLING TEAM

Introduction

The fragmented, thin, and often absent ice cover in the flaw lead allows solar radiation to reach the surface layer of the ocean where it triggers photosynthesis by microscopic algae. Team 4, Pelagic and Benthic Food Web, will investigate how and to what extent the microalgae growing in the flaw lead are exploited by animals living in the plankton (the zooplankton) and on the sea floor (the benthos). Our simple hypothesis is that, relative to adjacent ice-covered regions, enhanced algal production in the flaw lead translates into biological hot spots where higher zooplankton and benthos abundances prevail. We will also investigate how the Arctic cod, a central species in the Arctic food web, uses the flaw lead for feeding, overwintering, reproduction, and as a nursery ground for their young stages (http://www.ipy-cfl.ca/page1/page1.html).

General objectives

The general objective of our team during Leg 5 of CFL was to collect indices of secondary production in the water column in winter (December and January). Our sampling program was designed to be consistent with the overarching goal of ArcticNet project 1.4 led by Dr. J.-É. Tremblay (U. Laval) 'Marine productivity and sustained exploitation of emerging fisheries,' which is to assess the impact of sea-ice cover reduction and increasing sea temperatures on biological productivity, fisheries resources and marine mammal populations of the coastal Canadian Arctic. Since October 18th, the start date of the CFL program, we have focused on how physical processes moderate biogeochemical processes within the changing northern flaw lead ecosystem nearby Banks Island (Beaufort Sea). Our multidisciplinary ArcticNet-CFL team is strongly linked with Team 7 (Carbon Fluxes – Tremblay) of the CFL program. For this Leg 5 of CFL, sampling efforts were concentrated on the pelagic secondary producers.

The primary objectives of our team during CFL-5 were:

1- To assess zooplankton / fish abundance and diversity by using various plankton nets.
2- To track zooplankton / fish biomass and distribution with the EK60 Echosounder.

Our secondary field objectives were to collect and use the zooplankton samples for:

1- The cycling of contaminants in zooplankton (G. Stern, U. Manitoba)
2- Identification of the sources and pathways of omega-3 in the arctic marine food chain (J. Michaud, E. Dewaily and L. Fortier, U. Laval). This project is linked to the CFL-URSUK program and the ArcticNet theme 1.5, focusing on the importance of omega-3 fatty acid in the traditional diet of Inuit communities.
3- Assessment of the biomass and respiration rates of the zooplankton community by the Electron Transfer System (ETS) activity at selected stations (G. Darnis and L. Fortier).
4- Stable isotope analysis on the food web structure and carbon fluxes. This is a joint project between Team 4 and 7 of CFL (A. Forest, L. Fortier, J-E. Tremblay).
5- Copepod *in-situ* egg production (EPr) and gonad maturation of *Calanus hyperboreus* and *Metridia longa* (M. Ringuette, G. Darnis, L. Fortier).
6- Opportunistic genetic studies of amphipods (F. Dufresne and A. Radulovici, UQAR).

Sampling program

Leg-5 sampling program was oriented towards ice work, when the ship was stationary on an ice flow for periods of time varying from 1 day to a week. Zooplankton sampling was performed at 7 of the 9 floes (Fig. 1), as the ship only stopped briefly at the two unsampled floes. For this leg, vertical sampling of the water column from the ice was added to the usual moon pool zooplankton sampling activities. This later vertical net tow allowed sampling the first 10 m of the water column that cannot be sampled from the moon pool.

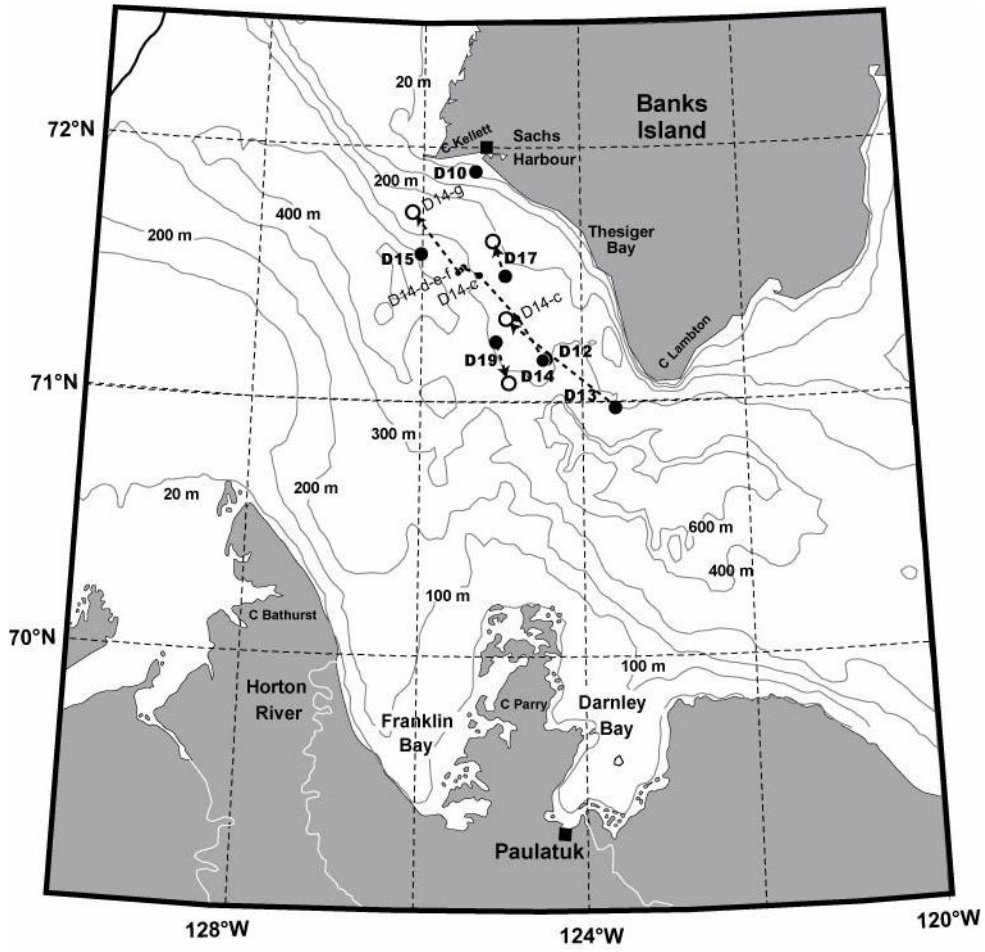

Fig. 1: Locations of CFL leg 5 drifting stations. Closed circles indicate the beginning of the rifting path while open circles marks the end.

Sampling gear and events

a) 1-m^2 Square net. Frame rigged with 1 square m^2 opening net (1 x 200, µm mesh), out-rigged with a 10 cm diameter net (50 µm) and equipped with a TSK flowmeter (Fig. 2a). This net is used for integrated water column sampling (summarized in Table 1). When deploying, downward winch speed was < 40 m/min to avoid mixing of the nets, and upward winch speed was 30 m/min. To obtain quantitative tow (i.e. for taxonomy and abundance estimates), the content of the 200 µm (TSK) and the 50 µm mesh-net were preserved in formaldehyde (Fortier). Qualitative tows (i.e. 'live tows') were also performed to obtain animals for contaminants, lipids, genetics, EPr and/or ETS studies. The weight and the wires out-rigging the net were replaced during the leg. On three occasions (2008D19-3, -4, and -5) the strong currents prevented the deployment of this net; the cast 2008D19-3 was annulled and casts2008D19-4 (taxonomy) and -5 (live tow) were performed using the heavier and thus more stable Hydrobios.

b) Hydrobios. Multi-depth plankton sampler (Fig. 1b) equipped with nine 200 µm-mesh nets (opening 0.5 m^2). This sampler allowed for depth-specific sampling of the water column. The *Hydrobios* is also equipped with a CTD to record water column properties while collecting biological samples. When deploying, downward winch speed was 40 m/min and the upward speed was 30 m/min. At most casts, the net collection was preserved in formaldehyde for taxonomic analysis but for some casts, the content of each net was divided: 50% for taxonomy (4% buffered formaldehyde), 25% for biomass estimates, and 25% for ETS analysis (Table 2). Note that the recurrent problem with the Hydrobios flowmeters observed during Legs 3 and 4 appear to be resolved, at the very least for the flowmeter

inside the Hydrobios frame; hence the TSK flowmeter that was placed on the Hydrobios during Legs 3 and 4 was removed.

c) Ring net. A 1-m diameter ring net equipped with a 200 □m mesh net and out-rigged with 10 cm diameter net (50 μm) and a flowmeter. This net was deployed twice per cast from a hole on the ice near the ship but at a site not influenced by the ship's presence (not downstream of it). Ice zooplankton sampling activities are summarized in Table 3. For the first station, a TSK flowmeter was used; however, it froze at each deployment and was replaced by a General Oceanic (G.O.) flowmeter filled with ethanol to prevent freezing. A Seabird 19 CTD was also fixed to the net frame, but was replaced by a RBR CTD after the first cast (2008D14-Ice1) when it was noticed that the pressure sensor was faulty and a depth profile could not be obtained. At each station cast, the first haul was from 10 m to the surface and the second haul from a maximum of 270 m to the surface. The net was lowered manually to the desired depth and pulled manually for the 10 m haul and using a snow mobile for the deep haul.

Overall, 105 sampling events occurred: 75 of the samples obtained were preserved for taxonomy and the remainder, the 'live tows', were used for further analysis and laboratory experiments as described above. Samples for lipid and stable isotope analysis were placed in cryovials and stored at –80˚C. A very small number of amphipods were preserved for genetic analysis as very few animals were collected and thus priority was given to the contaminant studies. Samples for contaminants were sorted and preserved by Gary Stern's team.

Laboratory analysis

Egg production rate experiments

Copepod *in-situ* egg production and gonad maturation (after Niehoff 1998) were monitored by incubating large calanoid species females at 0°C, a temperature similar to what they experience at depth. The presumed non-reproducing *Calanus glacialis* was monitored only twice during the leg in order to verify and confirm its non-reproductive state. *Metridia longa* and *C. hyperboreus* egg production was measured approximately every 5 or 6 days. *M. longa* did not produce any eggs but some females started to developed eggs by the end of January although gonadic index remained constantly low. Very few *C. hyperboreus*, females had matured eggs in late December, with less than 10% of the population having eggs in vitellogenesis. However, by mid-January, within only a week, the number of females with eggs in vitellogenesis increased rapidly from 18% to 60% and daily egg production rate went from 0 to 18 eggs f^{-1} d^{-1}. This corresponds only to the beginning of the reproduction season; rates should increase in the coming weeks.

Harsh winter conditions always provide difficulties in studying winter Arctic organisms. Because of this constraint, the metrics on the reproduction of *C. hyperboreus* is currently poorly documented. In order to measure the total production of *C. hyperboreus,* 50 immature females were placed in filtered seawater with their egg production monitored daily. Eggs produced were then used to measure the hatching rates for different eggs buoyancies (sinking vs. flotting). By the end of April we hope to get total reproductive output and the fate of this production. Finally an experiment was initiated to test the hypothesis arguing that *M. longa* can feed on *C. hyperboreus* eggs (Conover & Huntley 1991). The question here is if they simply feed on these eggs or if they use this consumption to fuel an early reproduction, before the onset of the algal production. Thirty females were fed every second day with a known number of freshly laid *C. hyperboreus* eggs. On the second day, the remaining eggs were counted and removed before providing new ones. Gonadic stages of *M. longa* were recorded weekly.

Biomass and Transfer System (ETS) activity

At five stations (Tables 1 and 2), samples were sorted for biomass and ETS activity essay. At these stations, each Hydrobios net was subdivided: 50% for taxonomy (i.e. preserved in formol); 25% for population biomass estimates; and 25% for ETS activity. To estimate biomass, the sub-sample (i.e. 25% of total sample) was fractionated with sieves in > 1000 □m and < 1000 □m size classes; these fractions were preserved at –20˚C. Subsamples for zooplankton population ETS activity essays (i.e. 25% of total sample) were also sieved into the same two size fractions. As no Sanyo incubator was available for the ETS experiments, samples were incubated in a Pyrex plate filled with water and heated to 40˚C on a hot plate. Temperature of this 'hot tub' prove to remain constant during the require incubation time. ETS experiments were also performed on individual copepods, females and copepodite stage 5, of *Calanus finmarchicus*, *C. hyperboreus* and *Metridia longa*

Acoustic monitoring

The Simrad EK-60 Echosounder of the *Amundsen* allowed our group to continuously monitor the spatial and vertical distribution of zooplankton and fish, the later mostly represented by Arctic cod (*Boreogadus saida*). The hull-mounted transducers are in operation 24 hours a day and will provide an extensive mapping of where the fishes were within the region of interest over a yearly cycle.

General Recommendations

As the drift of the ship while in a ice floe can be important, we recommend sampling every day with the Hydrobios and the 1-m^2 Square net in the moon pool and with the ring net from the ice. Sampling in the morning in the moon pool and from the ice in the afternoon proved to be the most convenient schedule for Leg 5.

Low temperature is the essence of all the measurements done with live animals. The very warm temperature in our laboratory may pose problems even to the environment chamber which shows difficulties to maintain the required 0°C. Setting the air conditioner system at 22°C remedied the problem. From now on, the AC should stay on and the laboratory door must remain closed.

When the ship is in transit, and the transit may last a few days, before stopping in a floe, particular attention should be given to the EK-60 sounder and the ADCP in order to make sure all sensors are cleared of ice before the shutting down of the engines. Otherwise the data recorded are simply unusable.

More importantly, enjoy this amazing experience in this harsh but beautiful environment, have fun and KEEP THE SPIRIT!!!

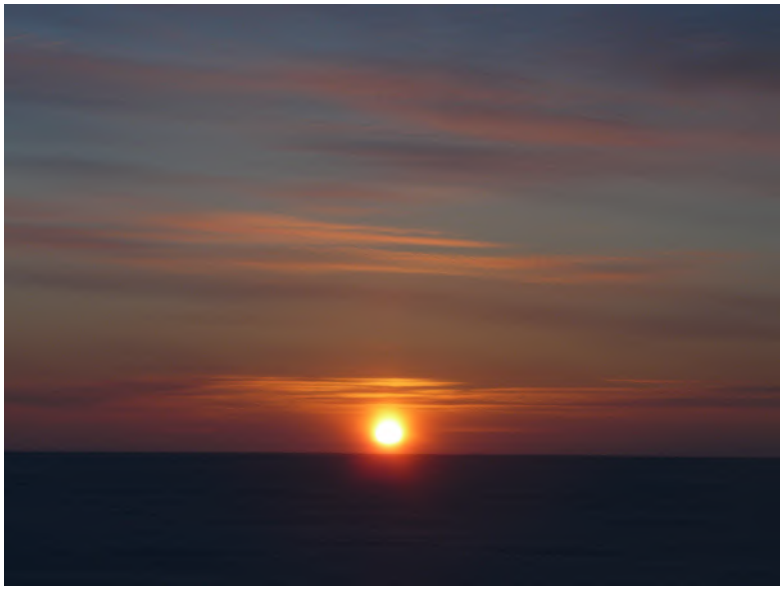
We thank the officers and the crew of *Amundsen* team B for their continuous effort and essential help; thank you for being able to repair or built anything we need! Special thanks to all who assisted us with sampling and digging holes in the ice and, finally, to Debbie Armstrong, Andrea Riedel and Jeff Latonas and the crew for being our bear watchers while we worked on the ice.

2.4. Team 6

2.4.1. Surface Meteorology and Flux Project

PI: Tim Papakyriakou, Centre for Earth Observation Science, University of Manitoba
Participants: Tim Papakyriakou, Bruce Johnson, Elizabeth Shadwick



Introduction
The surface meteorology and flux program (CFL Team 6) is designed to record basic meteorological conditions and to study exchanges of momentum, heat and mass across the atmosphere-sea ice-ocean interface. The main value of this program to the overarching objectives of Team 6 is the direct measurement of CO_2 fluxes.

Fluxes of CO_2 are measured by the eddy covariance technique, which is dependent only on atmospheric measurements. Although measurement of these fluxes is extremely useful information, it is essentially meaningless without an understanding of the processes (physical, biological and chemical) that drive gas exchange. In an open-ocean situation this context is largely provided by measurement of sea-surface pCO_2, but the situation becomes much more complex when a sea ice cover is included in the equation.

Micrometeorology and Eddy Covariance Flux Tower

Methods
The micrometeorological tower located on the front deck of the *Amundsen* (Fig. 1) provided continuous monitoring of meteorological variables and eddy covariance parameters. The tower consists of slow response sensors that record bulk meteorological conditions: wind speed and direction (1), air temperature and relative humidity (2), and surface skin temperature (10); and fast response sensors that record the eddy covariance parameters: CO_2/H_2O concentration (4 & 5), three-dimensional wind velocity (3), and three-dimensional ship motion (6). In addition, down-welling radiation sensors were installed on the roof of the wheelhouse to provide information on incoming longwave (7), shortwave (9), and photosynethetically active radiation (8). All data was logged to Campbell Scientific dataloggers; a model CR5000 logger was used for the fast response sensors, a CR1000 logger for the slow response meteorological sensors, and a CR23X for the radiation data. All loggers were synchronized to UTC time using the ship's GPS system as a reference.

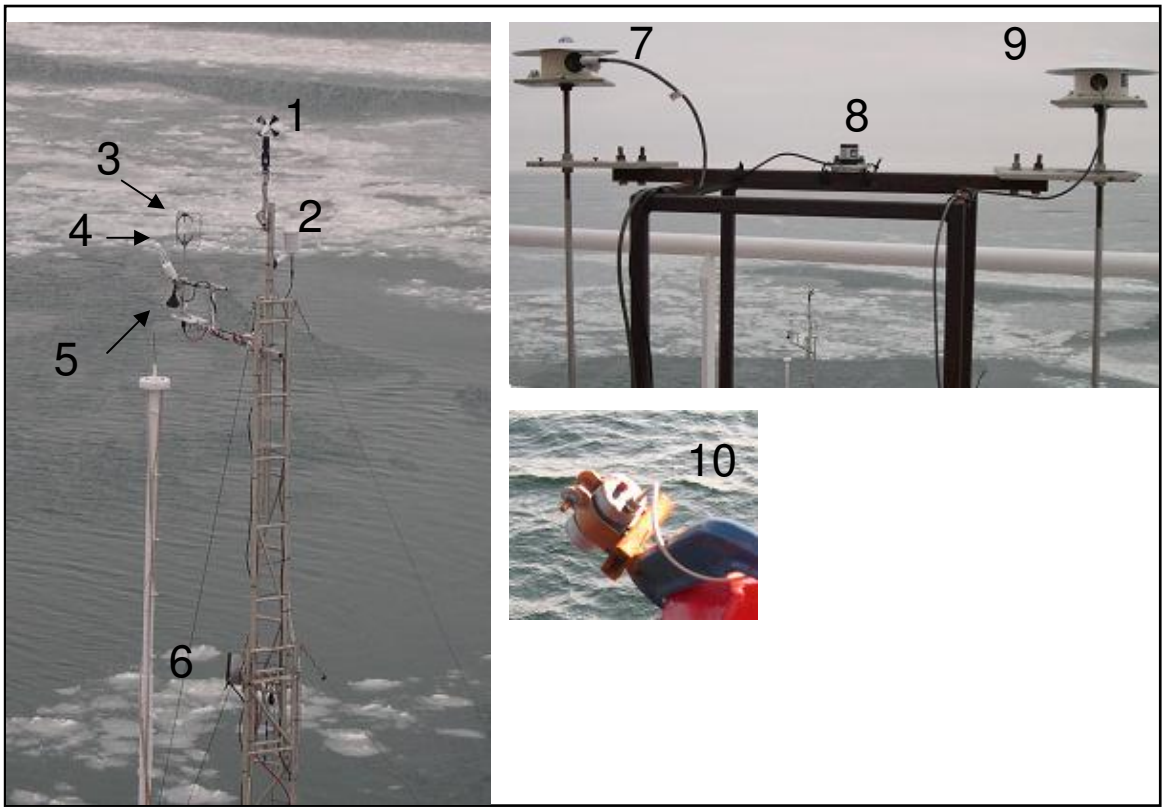


Fig. 1: Meteorology and flux program instrument setup.

The eddy covariance system on the tower makes use of two separate gas analyzers and a single three-dimensional sonic anemometer. The dual gas analyzers system allows us to make use of both closed-path and open-path eddy covariance systems. The open-path gas analyzer has the benefit of making measurements concurrently with the sonic anemometer, but the closed-path gas analyzer is not as easily disturbed by adverse weather conditions.

In order to make sure that the two systems are comparable, careful calibrations were performed on both instruments. The closed path system is based on a LI7000 gas analyzer that employs two optical cells, one of which was used to monitor the drift of the instrument by constantly passing a stream of ultra-high purity N_2. In addition, the sample cell of the instrument was calibrated daily using the ultra-high purity N_2 to zero the CO_2 and H_2O measurements, and a reference gas of known CO_2 concentration in air to span the instrument. Occasionally, a span calibration of the H_2O sensor was performed using a dew point generator (model LI-610). The open path gas analyzer (LI7500) could not be calibrated as conveniently, and so it was calibrated approximately every three weeks. In general, we find that this is effective for this particular instrument, which does not drift significantly over time.

Notes

The meteorological tower ran consistently for the duration of the leg (Dec 21 to Jan 31). However, for significant periods of time during this leg, data collected by some of the sensors were obviously erroneous due to atmospheric conditions. The most common problem encountered during this leg was frost covering the sensors due to the cold conditions. This problem most seriously affected the LI7500, which was very difficult to keep clean, and the radiation sensors, which were cleaned of frost on a daily basis. The frost problem also affected the sonic anemometer, but to a much lesser degree.

It was very difficult, and somewhat dangerous to climb the tower when everything was covered in frost. With this in mind, the tower was lowered to deck level whenever the sensors needed defrosting. Since we had two systems for measuring CO_2 and H_20 concentrations, and the LI7500 frosted over

very easily, the tower was generally only lowered for cleaning once the frost was bad enough to affect the sonic anemometer as well.

Ice-based Micrometeorology Tower

Methods

An 8-m tower was deployed on the ice in close proximity to the ship to measure meteorological data in conjunction with the data collected on the ship-based tower. The tower consisted of slow response sensors that recorded bulk meteorological conditions: wind speed and direction, air temperature and relative humidity at two heights, and surface skin temperature; and fast response sensors that recorded three-dimensional wind velocity. In addition, downward facing radiation sensors were installed on an adjacent 1m tall tower to provide information on upwelling longwave and shortwave radiation. All data was logged using a Campbell Scientific CR3000 datalogger that was synchronized to UTC time using the ship's GPS system.

Fig. 2: Ice-based meteorology tower at station D17 looking south.

Fig. 3. Ice-based meteorology tower at station D19 looking east towards ship.

Notes

The ice-based tower was deployed on three occasions during the latter half of the leg (i.e. Leg 5B) (refer to Table 1 for dates and specific location notes). The sensors on the tower were powered from a bank of 12V car batteries. Each morning a generator and charger was taken to the tower in order to

keep the batteries well charged. Other daily maintenance tasks included cleaning frost off the radiometers and IR transducer, and lowering the tower as necessary to clean frost off the sonic anemometer.

Deployment dates/locations

Table 1: Site and Deployment information for ice-based meteorology tower.

Site	Deployment Date	Removal Date	Notes
D14	Jan. 9	Jan. 11	Tower located ~200m north of ship; radiation sensors located ~8m northwest of main tower; sonic anemometer was not installed at this station
D17 (Fig. 2)	Jan. 15	Jan. 22	Tower located ~150m southeast of ship (ship's heading 90º); radiation sensors located ~8m west of main tower; sonic anemometer pointing to east
D19 (Fig. 3)	Jan. 25	Jan. 30	Tower located ~250m west of ship (ship's heading 235º); radiation sensors located ~6m east of main tower; sonic anemometer pointing to southeast

On-track *p*CO_2 System

Methods

A custom-built *p*CO_2 system was utilized on this leg to measure dissolved CO_2 at the sea surface in near real time. The system (Fig. 4) is located in the engine room of the *Amundsen*, and draws sample water from the ship's clean seawater intake. The water is passed into a sealed container through a shower head, maintaining a constant headspace. This set up allows the air in the headspace to come into equilibrium with the CO_2 concentration of the seawater, and the air is then cycled from the container into an LI7000 gas analyzer in a closed loop. Thermocouples are used to measure water temperature immediately before entering the equilibration chamber, and to measure the temperature of the air surrounding the chamber. All data are logged to a Campbell Scientific CR1000 datalogger.

The LI7000 gas analyzer was calibrated daily using ultra-high purity N_2 as a zero gas, and a gas with known CO_2 concentration in air as a span gas. Spanning of the H_2O channel was not necessary because a desiccant column removes H_2O from the air stream before passing into the sample cell. As with the closed-path eddy covariance system, a stream of N_2 is constantly cycled through the reference cell of the LI7000 to monitor and correct for drift of the instrument.

Fig. 4. The on-track pCO_2 system located in the engine room of the Amundsen.

Notes
The on-track pCO_2 system was active for the duration of the leg, with some minor interruptions for maintenance. Major interruptions in data collection were experienced when the ship was breaking ice, which either severely reduced the flow of water into the equilibration tank, or completely blocked it. In general, the system was turned off when the ship was breaking ice to prevent excessive wear and tear on the system's water pump.

During this leg, we experienced some major fluctuations in temperature where the system is located. The temperature was as high as 25º C at some times, and as low as –5º C on a couple of occasions. This proved disastrous during the night of Jan 19-20, when a suspected blockage in the outlet from the equilibration tank due to very low temperatures caused the closed air loop to become filled with water. Before this was discovered, seawater had entered the optical path of the LI7000.

The entire system was completely disassembled on Jan 20, and all the air lines were flushed with freshwater, and then dried with compressed air. The optical path of the LI7000 was removed from the instrument and cleaned thoroughly. The system was re-assembled and put back in to operation on Jan 23. Preliminary results seem to indicate that the cleaning was effective and the system is working properly.

The system was also shut down for ~ 6 hours on Jan 4 to exchange the gas analyzer and to clean the equilibration tank. The original LI7000 was experiencing problems with the DAC outputs which are used to send analog signals to the CR1000 datalogger. This problem was affecting all the analog input channels on the logger, so the decision was made to put a new analyzer into the system. Because the system was shut down, we also decided to clean the equilibration tank and shower head assembly. After cleaning, the system showed a marked improvement in water flow, indicating that cleaning should be done on a regular basis, at least once per leg.

2.4.2. CO_2 in Sea Ice

PI: Tim Papakyriakou, Centre for Earth Observation Science, University of Manitoba
Participants: Tim Papakyriakou, Bruce Johnson

Introduction
The primary focus of Team 6 is to gain a better understanding of the cycling of climatologically important gases in Arctic seas. A large base of knowledge already exists regarding air-sea gas exchange, but considerably less is known about the exchange of gases in an ice covered ocean. During CFL Leg 5, we continued a sampling program which was initiated during Leg 4 using silicon chambers (peepers).

Peepers

Methods
Silicon chambers (approximately 15 cm in length, 5 cm in diameter) were deployed in the ice, either in sackholes or in auger holes drilled completely through the ice. The silicone membrane is permeable to gas exchange. If the peeper is left in the ice for a long period of time (at least 24 h), the ambient gas in the peeper should come into equilibrium with gas that exists in brines and air pockets in the sea ice. Stainless steel tubing was used to sample the gas in the peepers with a gas analyzer (Licor model LI-820). The setup was designed to cycle air from the peepers through the gas analyzer in a closed loop. Data from the LI-820 was logged to a Campbell Scientific CR10X data logger at a frequency of 1 Hz. This allowed for the observation of a peak in CO_2 concentration as the gas in the peeper cycles through the gas analyzer. Although this eventually results in mixing of ambient atmosphere into the peeper chamber, we believe that the initial peak is representative of the CO_2 concentration in the ice.

Peeper notes
The peepers frozen into auger holes through to the ocean showed a continual increase of CO_2 concentration as long as they were left in the ice, which was 6 days at station D17 and 5 days at station D19.

With the peepers in sackholes, we had problems with brine filling the bottom of the holes. In many instances this caused the CO_2 concentration in the hole to exceed the limit of the gas analyzer (2000 ppm). This result led us to make the decision to move the peepers to shallower sackholes at station D17 on Jan 18, and to place the peepers in new sackholes each day at station D19. However, we still encountered problems with brine accumulation. The CO_2 concentration between peepers was quite variable depending on the amount of accumulated brine.

Deployment dates/locations

Table 1: Deployment date/location for peeper sampling.

Site	Deployment Date	Removal Date	Sample Dates/Time	Notes
D17	Jan 15	Jan 21	Jan 16, Jan 17 Jan 18, Jan 19 Jan 20, Jan 21	Deployed 3 peepers in auger holes to the ocean at depth of 20 cm. Deployed 3 peepers in 50 cm sackholes; these were removed and placed in 30 cm sackholes on Jan. 18.
D19	Jan 24	Jan 29	Jan 25, Jan 26 Jan 27, Jan 28 Jan 29	Deployed 3 peepers in auger holes to the ocean at depth of 20 cm. Deployed 3 peepers in 30 cm sackholes; these were removed after measurement and placed in new sackholes each day.

2.4.3. Dissolved Inorganic Carbon System (CFL Teams 6 & 7)

PIs: Helmuth Thomas, Department of Oceanography, Dalhousie University, Halifax, NS, Canada
Alfonso Mucci, Department of Earth & Planetary Sciences, McGill University, Montreal, Quebec, Canada

Participants: Elizabeth Shadwick (with PI Thomas), elizabeth.shadwick@dal.ca
Stelly Lefort (with PI Mucci)

The ocean's exchange of carbon dioxide with the atmosphere is governed by the biogeochemical cycling of carbon and physical processes throughout the water column, which determines the concentration of dissolved inorganic carbon in the surface waters. Of the seven relevant carbon system parameters, a minimum of two are needed to calculate the others and fully describe the inorganic carbon chemistry, over-determination of the system being beneficial. During CFL Leg 5, a total of 145 samples were analyzed for dissolved inorganic carbon (DIC) and total alkalinity (TA) and pH, yielding two/three relevant parameters.

Water samples were collected in parallel with the weekly, or once per station, nutrients rosette. Individual 250 ml bottles were used for DIC and TA, while samples for pH were collected in smaller plastic bottles. DIC samples were the first in the set to be taken from the Niskin bottles (preceded only by dissolved oxygen), with pH and TA following immediately at individual casts and depths. These

samples were then spiked with $HgCl_2$ and taken to the lab for analysis. Samples not analyzed right away were stored in the dark at 4°C.

When the contaminants group was sampling for mercury, DIC and TA samples were not spiked with $HgCl_2$ but analyzed within 24 hours of sampling. In the case of pH, the bottles were spiked outside of the rosette room, immediately after sampling.

Since we were using the moon pool for rosette sampling during Leg 5, the top 10 meters of the water column were missed. In addition, we found that the 10-meter depth samples were often contaminated. As a result, the final rosette sample was taken at 12 meters, and surface water sampling took place on the ice the same morning as the rosette sampling.

Surface water samples were collected from the zooplankton hole using a small pump run on a gas generator and lowered by hand to 1.5 or 2 meters below the surface. Bottles were filled using standard methods on the ice, and the samples returned to the ship immediately or kept from freezing in a cooler using hot water bottles. A 12 L Niskin bottle was also used to sample at a depth of approximately 7 m, following a CTD cast from the surface to 10 meters. The Niskin bottle was brought directly back to the ship for sampling, as the spigot would freeze when the bottle came out of the water.

DIC and TA were analyzed on board using a VINDTA 3C (Versatile Instrument for the Determination of Titration Alkalinity) by Marianda, and a TIM 865 automatic titrator from Radiometer Analytical. TA was determined by titrating a volumetrically accurate subsample using HCl as titrant. For DIC analysis, a volumetrically determined subsample was acidified with 8.5% H_3PO_4 to convert all inorganic carbon into gaseous CO_2. The CO_2 was then stripped out of the sample using ultra-pure N2 gas, transferred into a coulometric titration cell and detected using the coulometric method (Johnson et al., 1993). Samples were analyzed for pH using a HP 8453 spectrophotometer; pH was calculated using the absorbance measurements obtained from the coloration of water samples with Phenol Red and Cresol Purple.

In addition to water column sampling, an attempt was made to continue (to a lesser extent) the ice core work initiated by Team 6 on the previous leg. To this end, one core was collected at each new drift station. The top, middle, and bottom 10 cm of the core were cut and placed in plastic Tedlar bags – gas impermeable, with a clamp type seal and small spigot for withdrawing air or water. The core sections were laid out to thaw then transferred to DIC bottles. These samples were analyzed for DIC, TA, and conductivity.

2.4.4. Barium

PI: Helmuth Thomas
Participant: Elizabeth Shadwick, Department of Oceanography, Dalhousie University, Halifax,N S, Canada, elizabeth.shadwick@dal.ca,

In the Canadian Arctic, barium (Ba) is mainly released from the North American continent and can therefore be used as a tracer for terrestrial freshwater input. Together with ^{18}O, a tracer for freshwater input from precipitation and ice melt, all freshwater sources to the Arctic can be quantified.

Throughout Leg 5, samples for barium were taken from the rosette parallel to samples for ^{18}O, at approximate depths 10, 20, 50, 70, 100, 140, 200 and 300 m. Small plastic bottles (15 ml volume) were rinsed three times, then filled and spiked with 15 µl concentrated HCl. Sample bottles were then sealed with parafilm and kept for later analysis using isotope dilution mass spectrometry.

Table 1: Stations sampled for Barium.

2008-19D	26/01/08	71°6.650	124°56.698

Water was sampled at the following depths: the depth where salinity was 33.1 and at 10, 20, 30, 40, 50, 60, 80, 100, 120, 140, 160, 180, 200, 250, 300 and every 100 m down to the bottom. The nutrient and urea samples were all frozen and will be analyzed on a future leg.

Sea ice

PI: Christine Michel (Fisheries & Oceans Canada, Winnipeg)
christine.michel@dfo-mpo.gc.ca

Participants: Andrea Niemi (Fisheries & Oceans Canada, Winnipeg) andrea.niemi@dfo-mpo.gc.ca;
Greg Niemi (Université du Québec à Rimouski, Rimouski) gniemi@mts.net

Collaboration: Philippe Archambault (UQAR), Michel Gosselin (UQAR), Christian Nozais (UQAR), Michel Poulin (CMN), Roxane Maranger (U of M), Jean-Eric Tremblay (Laval University), David Barber (U of Manitoba), Tim Papakyriakou (U of Manitoba), Jody Deming (U of Washington)

Subproject: Pathways of cycling and export of organic material in the sea ice and flaw lead system.

The overall objective of this project is to further our understanding of the cycling and downward export of organic material in the sea ice, at the ice-water interface, and in the flaw lead system. Sea ice contains a diverse community of organisms which is integral to the cycling of organic matter in the Arctic Ocean. Microorganisms are incorporated into the sea ice during periods of ice formation (Riedel et al. 2007). During the spring, there is a conspicuous ice algal bloom that develops in response to increasing light availability. Sea-ice production is coupled with both pelagic and benthic production (e.g. Michel et al. 1996, Renaud et al. 2007) and may contribute 25% or more to total Arctic primary production (Legendre et al. 1992, Gosselin et al. 1997). However, little is known about the abundance and distribution of sea-ice carbon constituents within the flaw lead and during the dark winter period. Thus the objective for the Leg 5 of the CFL system study was to investigate dissolved and particulate sea-ice organic carbon pools during the dark winter period. Heterotrophic microbial carbon cycling and cell survival strategies (i.e. exopolymer cryoprotection) would also be assessed. This research will provide a better understanding of annual cycles of sea-ice carbon cycling.

Sample collection

Sea ice

Sea-ice associated samples collected during Leg 5 are summarized in Table 1. Complete ice cores were collected to obtain vertical profiles of the variables listed in Table 2, including nutrients and dissolved organic carbon (DOC) profiles. Therefore, the ice sections for the vertical profiles were melted in sterile Whirl-Pak bags without the addition of filtered seawater. The cores were cut into 10 cm sections, except for the bottom section (nearest the water) that was cut into a 0–3 cm and 3–10 cm section. Three complete cores were collected on each sampling day and the corresponding sections were combined to obtain enough volume for all analyses.

Bottom ice samples (0–3 cm and 3–10 cm sections only) were also collected on each sampling day. These samples were melted with the addition of filtered seawater (0.2 µm polycarbonate membrane filters) to minimize osmotic stress during the melting process (Garrison & Buck 1986). Again 3 cores were combined to obtain enough volume for the analyses (Table 2). All ice cores were collected with a manual ice corer (Mark II coring system, 9 cm internal diameter, Kovacs Enterprise). With each ice collection we measured the freeboard and ice and snow thickness.

Spatial variability of bottom ice carbon was also investigated on three occasions. We used a triangular sampling plan to assess the variability of chlorophyll *a* (chl *a*) and particulate organic carbon (POC) concentrations at 5, 3 and 1.5 m scales. At D19 we also sampled bottom sea ice from under different snow cover (12 versus 5 cm). In the spring, snow cover greatly influences sea-ice biomass and species composition due to light attenuation. We wanted to determine if there was detectable spatial variation in sea-ice constituents that could be linked to snow cover variability in the winter. Such variability could possibly be related to different rates of ice growth linked to the insulating properties of snow cover. Finally, newly formed sea ice (1 and 3 cm thick) from a flaw lead was collected on two occasions using a strainer. For these samples, surface water for analyses and ice melting was collected using a bucket.

Brine and surface water
On the majority of ice sampling days, interface water and brine samples were also collected (Table 1). The water was collected from the ice-water interface using an under-ice arm and hand pump. This water was analyzed as described in Table 2 and a portion was filtered for the melting of the bottom ice samples.

Partial ice cores were removed to make sac holes into which brine could drain. The brine holes were covered with Styrofoam plugs and left to drain for 2 to 24 h before the brine was collected with a sterile syringe. A minimum of 10 cm of ice remained in all brine holes to limit the infusion of surface water.

Table 1. Summary of sea-ice associated sampling conducting during Leg 5. Asterisk (*) indicates that bottom ice samples were collected at two ice thickness sites with high and low snow cover, respectively.

			Samples collected					
Date (mm/dd/yr)	Drift Station	Ice thickness (cm)	Ice profile	Bottom Ice	Spatial survey	Brine	Surface water	Trap deployment
12/25/07	D11	30	x	x		x	x	
12/27/07	D12	70						x
12/29/07	D12	70	x	x		x	x	
01/02/08	D14	104	x	x		x	x

Under-ice sediment traps
On three occasions short-term particle interceptor traps (sediment traps) were deployed at 1 m from the bottom of the ice. We wished to deploy the traps for a 5 to 6 d period to obtain a winter baseline of sinking organic matter. The first deployment (D12) lasted for only 2 d due to ice instability. The second deployment (D14) lasted for approximately 4 d, ending again when the ship was repositioned. During these deployments we were drifting as fast as 0.7 knots. At D17 we were able to install the traps for a full 6 d and the rate of drift was much slower. At D14 we "caught" two juvenile Arctic Cod in the sediment traps (given to the zooplankton team).

The sediment traps were PVC cylinders with an internal diameter of 10 cm and a height/diameter ratio of 7. Before each deployment, deep water (>200 m) was collected and filtered through a 0.2 µm polycarbonate membrane filter. The traps were filled with the filtered deep water so that the trap water would be denser than the surface waters in which the traps were deployed. Prior to deployment, the filtered seawater was analyzed for DOC, salinity, conductivity and temperature. Upon recovery of the traps, the total volume (~5.6 L) was used to assess POC, DOC and total chl *a* concentrations. Salinity, conductivity and temperature were again measured. Cell samples were also collected for fecal pellet (microscopic counts) and bacterial (flow cytometry) abundances as well as cell taxonomy (preserved with acidic lugols). Slides of exopolymeric substances (EPS) were prepared to assess their association with sinking material.

Rosette
DOC samples were collected at each depth of the five nutrient rosettes of Leg 5 (casts 018, 030, 036, 088, 123 and 142). Water was also collected at 10 and 40 m for the measurement of total chl *a* concentrations and preservation of cell taxonomy samples (M. Poulin collaboration).

Sample analyses
The variables assessed for the ice associated samples are summarized in Table 2. The methods used for these analyses are briefly described below.

Table 2. Summary of variables analyzed for sea-ice, brine, surface water and under-ice sediment trap samples during leg 5 of CFL. [1]samples collected for the enumeration of both bacteria and protists, [2]cell taxonomy includes counts of fecal pellets from under-ice sediment traps

	Ice profile	Bottom Ice	Sea-ice spatial survey	Brine	Surface water	Under-ice trap
Salinity	x	x		x	X	x
Conductivity	x	x		x	X	x
Temperature	x	x		x	X	x
pH	x	x		x	X	
Inorganic nutrients	x	x		x	X	
DOC/DON	x	x		x	X	x
POC/PON		x	x		X	x
Chl a/pheopigments	x	x	x	x	X	x
Flow cytometry[1]	x	x		x	X	x
Epifluorescence[1]	x	x		x	X	
EPS	x				X	
EPS slides	x			x	X	x
Cell taxonomy[2]	x	x		x	X	x
Bacterial activity		x		x	X	

DON/PON = dissolved/particulate organic nitrogen

Salinity, conductivity and temperature were determined with the hand-held meter (HACH Sension 5) provided by the physics/contaminant ice coring teams. When enough volume was present, a subsample was also saved (in cold room) for later determination of salinity with the Autosal (Model 8400B) analyzer. A desk-top meter was used to measure pH (Denver Instrument 250) after calibration with 3, 7 and 10 pH standards.

Subsamples for inorganic nutrients (NH_4, NO_2, NO_3, $Si(OH)_4$ and PO_4) were frozen in liquid nitrogen and then stored at –80°C for later analysis. There was no pre-filtration of the nutrient samples. When fresh ice samples were available on the nutrient rosette sampling day, a subsample of melted 0–3 cm or 3–10 cm ice was given to the nutrient team (Loic/Véronique) to determine the NH_4 concentration.

Duplicate DOC subsamples were filtered through precombusted Whatman GF/F filters. The filtrate was acidified with 50% H_2PO_4 and stored at 4ºC in the dark. POC subsamples were filtered onto precombusted Whatman GF/F filters and dried at 60°C for 24 h. We determined total chl *a* and phaeopigment concentrations using the onboard fluorometer (10AU Turner Designs). Duplicate subsamples were filtered on Whatman GF/F filters (total chl *a*) after which the chl *a* was extracted for 18 to 24 h in 90% acetone.

Cell samples for taxonomy (20 to 250 ml) were preserved with either acidic lugols or buffered formaldehyde. Bacterial and protist samples were collected for both epifluorescent microscopy and flow cytometery analyses. Subsamples for flow cytometery (heterotrophic bacteria and pico/nanoplankton) were preserved with a final concentration of 0.1% glutaraldehyde and stored at –80°C. Subsamples for epifluorescence were preserved with formaldehyde (1% final concentration),

stained with DAPI (4, 6-diamidino-2-phenylindole), at a final concentration of 1 µg ml^{-1}, and filtered onto 0.2 µm black Nuclepore filters. The prepared slides were stored at –80°C. The presence of active bacteria was investigated by incubating subsamples with 5-cyano-2,3-ditolyl tetrazolium chloride (CTC, final concentration 5 mM). The samples were incubated for 3 h at –1.5°C in the dark. Samples were preserved with a 5% final concentration of formalin and frozen.

EPS, defined as >0.4 µm acidic exopolysaccharides, were assessed with two methods. Bulk concentrations were estimated by Alcian blue staining of samples filtered on 47 mm 0.4 µm Nuclepore filters. EPS concentrations were also measured colorimetrically (787 nm, onboard JENWAY 6300 spectrophotometer) after a 2 h extraction in 80% H_2SO_4. EPS slides were also prepared by filtering subsamples on 25 mm 0.4 µm filters and staining with Alcian blue. The slides were prepared according to Logan et al. (1994), allowing for the observation of EPS using brightfield microscopy.

Preliminary observations

This leg of CFL provided a great opportunity to access different types of winter ice. The collection of the new ice was especially interesting. By visually inspecting filtered material (i.e. the GFF filters) it was obvious that the amount of organic/inorganic material in samples of winter sea ice and surface waters is quite variable within the flaw lead area we visited. It was also evident that material was still being incorporated into newly forming sea ice of the flaw lead. Chl *a* concentrations were low (<0.5 µg l^{-1}) and vertical profiles appeared to be similar to sea-ice salinity trends (Fig. 1). Highest chl *a* concentrations were found closest to the ice-water interface.

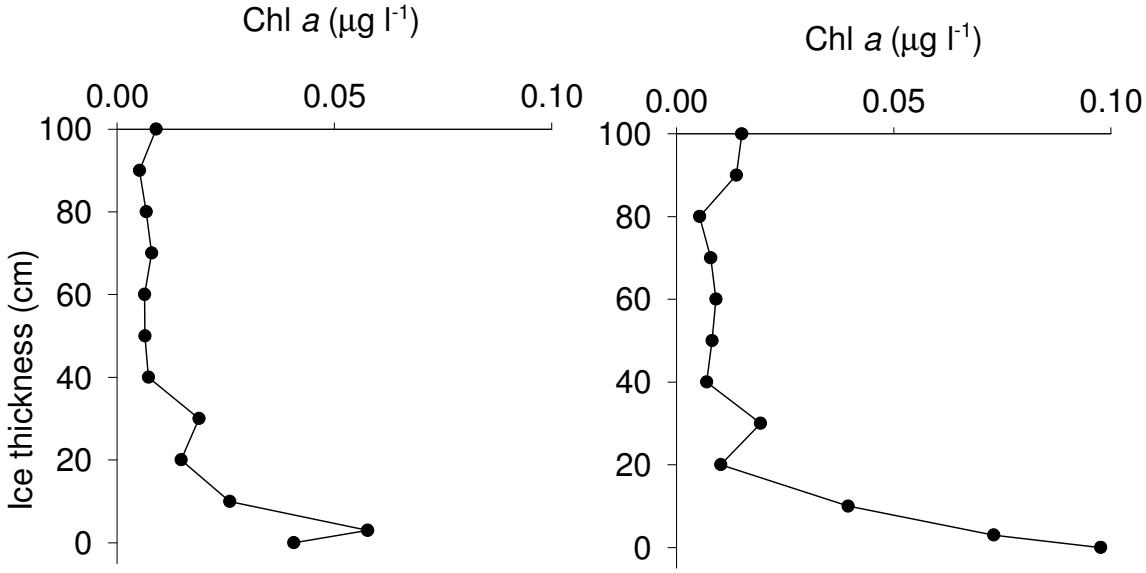

Figure 1. Vertical profiles of sea-ice chlorophyll *a* (chl *a*) concentrations at station D14. The ice thickness scale starts (0) at the ice-water interface

Acknowledgements

We greatly acknowledge all the hard work of the officers and crew during this leg. We also thank Tim and Jody for all their time and effort. We appreciate the support of the physics/contaminants ice coring teams and the use of their salinity meter. It was great to work with you. We'd also like to thank the zooplankton team for their ice hole assistance.

2.5.2. Marine Molecular Microbiology Group

PIs: Connie Lovejoy, Université Laval, Quebec City, Canada, and Carles Pedrós Alió, Institute de Sciences Del Mar, Barcelona, Catalonia, Spain
Participants: Montserrat Coll (Pedrós-Alió team), Maria Raquel Rodriguez (Pedrós-Alió team), Ramon Terrado (Lovejoy team)

Introduction
Microorganisms (or microbes) are defined here as including all members of the domains of Archaea and Bacteria and the single-celled members of the Eukarya. As such a large group, microbes accomplish a multitude of different biological and biogeochemical processes that are key for the ecosystem. They lie at the base of the trophic web in the Arctic Ocean (as in any environment), which includes organisms that span a size range of seven orders of magnitude, from the smallest microbes, less than 1 µm, to the largest mammals on the scale of meters. All of these organisms are affected by the low temperatures and ice cover of the Arctic, as well as the lack of light during winter. Comparing the species composition and activities of microbial communities across diverse physical-chemical regimes helps to determine the importance of different forces to the microbial use and recycling of organic and inorganic matter and consequent influences on higher trophic levels of the food web. Such knowledge is needed to better predict the consequences of environmental changes, natural or anthropogenic, to trophic dynamics and ecosystems. It will also help us to evaluate the system's ability to buffer changes on short and long timescales.

Objectives
Our group had an ambitious sampling program for this leg. The protocols employed covered the work of 4 teams – Corina Brussard, Connie Lovejoy, Roxanne Maranger and Carles Pedrós-Alió – and many different aspects of the microbial world. Our overall objective was to gain a detailed view of the microbial diversity and processes occurring during the winter season.

Sampling
The sampling for this leg took place to the south and southwest off the coast of Banks Island. The comparison of samples collected during the different winter-season legs will allow a better understanding of the seasonal dynamic, while the comparison of the different geographical areas will provide valuable information on the diversity and distribution of microbes.

In total we sampled 12 stations. Date and location of the stations can be found in Table 1. Our sampling strategy was to obtain microbiological data from specific water masses through the water column with a special focus on the nitracline, the upper mixed layer, and deep waters. These water masses were identified during the downcast of the CTD, based on the readouts from the temperature, salinity, oxygen, nitrate, fluorescence, transmissometer and pH probes.

On an opportunistic basis, surface water (2-m depth) was collected off ship through a hole in the ice. These samples will be compared to the surface water (10-m depth) collected from the moon pool inside the ship.

Variables Sampled

Here we provide a brief description of the variables measured and protocols applied to the various samples collected, which are summarized in Table 2.

1. DNA

Samples for DNA were collected on every station at 4 different depths. Seawater was prefiltered through a 50 µm mesh to exclude larger organisms, then through a 3 µm polycarbonate filter followed by a 0.2 µm filter. This sampling protocol yielded two different samples, one containing the DNA from 50 µm to 3 µm fraction ("large fraction") and one containing the 3 µm to 0.2 µm fraction ("small fraction'). After collection samples were stored at –80 ºC for later processing in the Lovejoy laboratory at the Université Laval. These samples will give valuable information on the biodiversity and distribution of microorganisms.

a. Metagenomic DNA sampling

On station 2008-D17, in addition to sampling 4 different depths for DNA, all water from cast 119 was collected at a single depth (15 m) and a total of 24 liters were filtered for DNA. This specific sample will be used to construct a metagenomic library once the sample is processed in the laboratory off the ship.

2. RNA

Samples for RNA were collected on every station at 4 different depths. Seawater was prefiltered through a 50 µm mesh to exclude larger organisms, then filtered through a 3 µm polycarbonate filter followed by a 0.2 µm filter. This sampling protocol yielded two different samples, one containing the RNA from 50 µm to 3 µm fraction ("large fraction") and one containing the 3 µm to 0.2 µm fraction ("small fraction"). After collection samples were stored at –80 ºC for later processing in the Lovejoy laboratory at the Université Laval. These samples will give valuable information on the spatial expression of key genes.

3. Chlorophyll

Samples for chlorophyll analysis were taken on each station at six different depths. Two fractions were collected, one for the total fraction (from 200 µm to 0.6 µm) and one for the small fraction (from 3 µm to 0.6 µm). Samples were extracted onboard using acetone and read using a Turner TD-700 fluorometer.

4. HPLC

Samples for High Performance Liquid Chromatography (HPLC) analysis were taken on each station at six different depths. Two fractions were collected, one for the total fraction (from 200 µm to 0.6 µm) and one for the small fraction (from 3 µm to 0.6 µm). Samples were stored at –80 ºC for later analysis off the ship.

5. Viruses

Samples for several different variables related to viruses were collected.

a. Viral abundance

Samples were collected at 6 depths at every station for analysis by flow cytometry.

b. Burst Size

Samples were also collected at 6 depths for analysis by transmission electronic microscopy.

c. Viral production

Virus-free seawater was added to a bacterial concentrate and incubated with mitomycin C for 12 hours. Blank samples without mitomycin C were incubated for comparison with the mitomycin C samples in order to obtain an estimate of virus production on infected cells (lytic and lysogenic cycles). Subsamples were taken every 3 hours for analysis by flow cytometry.

d. Viral diversity

Two liters of surface seawater were concentrated to 50 mL using a Vivaflow system (30 kd cartridge). This concentrate will be used to analyze the diversity of viruses present.

6. Silica isotopes

Three different depths were sampled in order to obtain information on silica isotopes. Seawater was filtered through a 0.6 µm polycarbonate filter. Both filters and the filtered seawater filtered were stored for later processing.

7. Organic matter and phosphorus

Samples for the analysis of organic matter were collected on drift station 2008-D19. Using pre-combusted GF/F filters (47 mm diameter) in a passive filtration system (by gravity) samples for dissolved organic matter (DOM), total organic carbon (TOC), amino acids and carbohydrates were taken. Samples for total phosphorus without filtration were also collected.

8. Bacterial abundance (Bacteria and Archaea)

Samples for obtaining estimates of total bacterial abundance were prepared by filtering 20 ml of seawater fixed with formaldehyde, then staining with DAPI (which binds to the DNA). DAPI-stained slides for microscopy were prepared on all stations at 6 different depths and stored frozen (–20°C) for later cell counting. At some stations, samples were prepared using glutaraldehyde instead of formaldehyde as the fixative. These slides were frozen at –20ºC and counted onboard using the Olympus BX51 epifluorescence microscope onboard. The profile for station 200-14D can be found in Fig. 1.

9. Abundance of eukaryotic microbes

Samples for obtaining estimates of eukaryotic abundance were prepared by filtering 100 ml of seawater fixed with glutaraldehyde, then stained with DAPI (which binds to the DNA). DAPI-stained slides for microscopy were prepared on all stations at six different depths. These slides were frozen at –20ºC and counted onboard using the Olympus BX51 epifluorescence microscope onboard. Vertical profiles for the drift station 2008-14D can be found in Fig. 2 and 3.

10. Ciliates

Samples for estimating the abundance and diversity of ciliates were collected and preserved using a Lugol acid solution. These samples will be analyzed off the ship.

11. FISH: eukaryotes

Fluorescent In Situ Hybridization (FISH) is a powerful technique or quantifying specific groups of microorganisms. Samples for FISH were collected on all stations at 6 different depths. Samples were stored at –80ºC until analysis off the ship.

12. CARD–FISH: Bacteria and Archaea

Samples for the abundance and distribution of specific groups of Bacteria and Archaea were collected on all stations at 6 different depths. These samples were frozen at –20ºC until analysis with various oligonucleotide probes off the ship.

13. MarFISH: Bacteria and Archaea

Incubations with a radioactive substrate were carried out to detect active Bacteria and Archaea. Combined with the FISH technique this approach can give information on the phylogenetic identity of the active microorganisms. Subsamples collected via this technique were stored at –80ºC for later analysis off the ship.

14. Bacterivory – grazing on FLB

In order to acquire values of ingestion rates of bacteria by heterotrophic eukaryotes, Fluorescent Labelled Bacteria (FLB) obtained from a culture of *Brevundimonas diminuta* were used in bacterial grazing experiments. Three replicates and a 0.2 µm filtered seawater control were amended with 10^5 FLB/ml. Subsamples for microscopic observation of flagellates and bacteria and for measurements of bacterial production were collected at the beginning and after 48 hours of incubation at seawater temperature (in the cold room).

15. Herbivory – grazing on *Micromonas*

Two grazing experiments with the *Micromonas* strain RCC497 were performed in order to calculate an ingestion rate of *Micromonas* cells by heterotrophic flagellates. For each experiment, two replicates of 2000 ml seawater, prefiltered through a 200 µm filter, were incubated for 96 hours at surface seawater temperature (–1.4ºC). A control of 0.2 µm filtered seawater was run in parallel under the same conditions. Samples for FISH (to observe *Micromonas* ingestion) and flow cytometry (to observe *Micromonas* disappearance) were taken. Incubations were run during the second half of the leg, as the *Micromonas* cultures brought from Barcelona first had to adapt to the incubation conditions provided onboard. Experiments were conducted once exponential growth of the cultures was achieved.

16. Bacterial production

Bacterial production rates were measured using the leucine incorporation method (^{3}H labelled leucine) with 4 hours of incubation at 2°C. Rates of incorporation of radiolabelled leucine were measured using the scintillation counter onboard. Some problems were experienced with the scintillation counter at the beginning of the leg, but they were resolved with the help of Steeve Gagné.

17. Respiration

Bacterial/community respiration rates were measured using the FIBOX, which measures O_2 depletion over time using sensors glued to the bottom of 500 ml Erlenmeyer flasks. The consumption of O2 can be converted to CO2 production to compare carbon respiration rate to bacterial carbon production rates.

18. ETS

Due to the expected low respiration rates in Arctic winter waters, the ETS (electron transport system) method was also employed as a back-up method to obtain proxies for respiration rates. For this method, a large quantity (8L-10L) of seawater was filtered through GF/F filters to collect live cells and freeze them (–80°C) as quickly as possible. Once off the ship, filters will be thawed and the living cells will be subjected to various enzymatic tests to measure activity.

19. N_2O

Dissolved N2O measurements were carried out using the headspace equilibration method with 1.1 L of seawater. Three samples were taken from 3 depths for N2O analysis off the ship using an electron capture detector (GC).

Experimental program

1. BrdU incubations

Incubations with the thymidine analogue bromodeoxiuridine (BrdU) were carried out during 3 weeks. On a periodic basis, subsamples for DNA were taken. Once off the ship these samples can be used to determine the identity of the microbes that were active during the incubations, by applying antibodies specific for the BrdU incorporated into the DNA of the microorganisms.

2. Archaeal enrichments

Pierre Galand had started Archaeal enrichments on Leg 4. Two different depths of the upper mixed layer were sampled and 4 incubations initiated. Two incubations were amended with ammonia and phosphate, while the other two were not supplemented with any nutrients. In the middle of Leg 5, subsamples for FISH and CARD-FISH analyses were taken. These incubations were left to continue shipboard and will be terminated on Leg 6 by Laura Alonso.

3. Unamended seawater incubations

Surface seawater was collected, filtered with a 3 µm filter and incubated for 18 days at a surface seawater temperature. Subsamples for DNA, epifluorescence microscopy and fluorescence in situ hybridization (FISH) were taken every 2 days. In similar previous studies of other seawater samples (Norwegian Sea, Mediterranean Sea and Indian Ocean) this simple treatment had been observed to promote the growth of heterotrophic flagellates at rates (0.3 to 1.2 d^{-1}) typical of natural assemblages. By incubating 3 µm-filtered seawater in the dark, we expect bacteria growing on autochthonous substrates to support a moderate pulse of heterotrophic flagellates, which can then be identified with molecular tools. The subsamples from this experiment will be analyzed in Barcelona.

Other activities

The whole team participated in all of the planned social activities of the ship. Montserrat and Raquel also wrote a dispatch in 3 languages (English, Spanish, Catalan) for the CFL webpage. Ramon was responsible for maintenance of the MilliQ system. The system needs to have the UV lamp changed, but a replacement was not available onboard (expected for Leg 6). Ramon also helped the zooplankton team to dig holes in the ice and to sample. He also provided 0.2 µm filtered seawater. During the latter half of the leg, he continued a Spanish course that had been started by Laura Sims during the first 3 weeks.

Acknowledgments

The cruise was a success and we are grateful to our Chief Scientists, Tim Papakyriaku and Jody Deming, Captain Lise Marchand and the crew of the *Amundsen* for the excellent work accomplished during Leg 5. We thank Loïc Degroote and Veronique Lago for CTD Rosette operations, Steeve Gagné for technical assistance, and Debbie Armstrong and Elisabeth Shadwick for assistance with

under-ice surface water sampling.

2.5.3. Carbon Flux, Exopolymers & Extremophiles

PI: Jody Deming
Participants: Jody Deming (Chief Scientist), Marcela Ewert Sarmiento and Minhui Lin

Group members: Jody Deming (PI), Eric Collins (graduate student Leg 4), Marcela Ewert Sarmiento (graduate student Leg 5B), Minhui Lin (graduate student Leg 5B), Colleen Evans Kellogg (graduate student, Leg 9), Shelly Carpenter (technician, Legs 9-10)

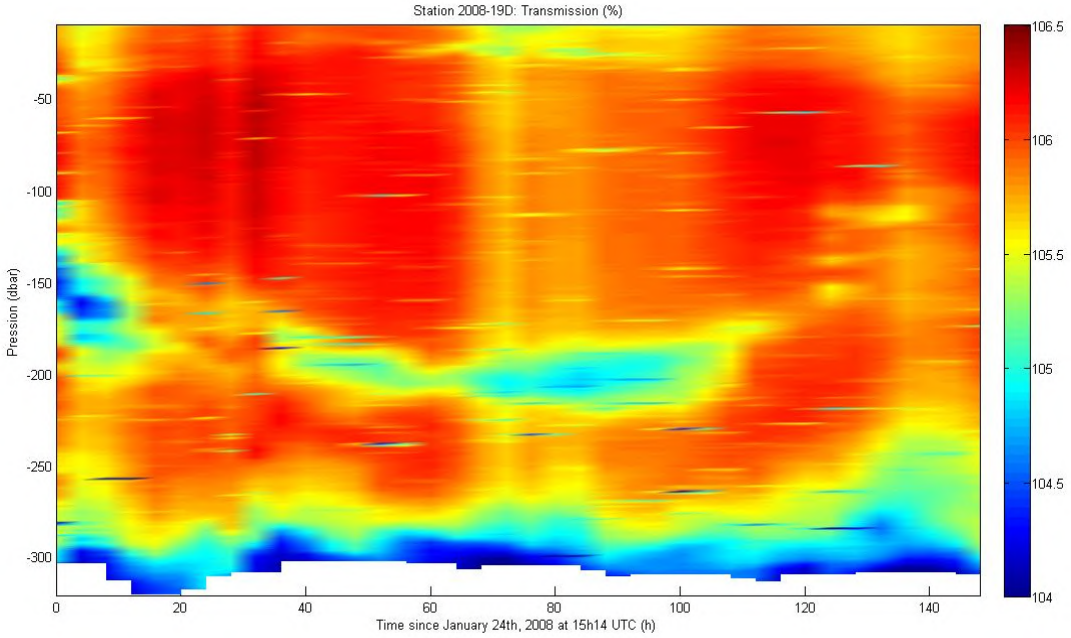
University of Washington
School of Oceanography and Astrobiology Program

Carbon flux (Kellogg and Deming)

Building on prior work that had identified nepheloid layers as targets of interest for carbon flux in this region (Wells et al. 2006; Forest et al. 2006), seawater samples were collected from the Rosette in an attempt to detect and track a nepheloid layer of resuspended sediments and their associated organics and microbial assemblages moving laterally across shelf. Nepheloid layers were identified by a reduction in transmissivity and confirmed by the presence of angular shaped sediment grains on filters after filtering 30-70 liters. Samples collected were processed for later analyses of Bacteria and Archaea and of lipids that would indicate the presence of terrestrial Archaea. In general, nepheloid layers in the study region were weak, if present at all. While on station D19, however, a mid-water layer (in addition to the typical bottom layer) persisted in the beam transmission profiles at a depth of about 200 m for about 5 days, as shown below in the temporal plot of transmissivity data kindly provided by Veronique Lago.

Ultimately, five samples were processed by Min for further analysis by Colleen and Shelly, who will join later legs for further studies related to the role of particle-associated microbes in attenuating carbon fluxes:

Date	Station	Cast #	Depth (m)	Nepheloid layer
20 Jan 2008	D17	110	218	Bottom water
25 Jan 2008	D19	136	309	Bottom water
28 Jan 2008	D19	149	193	Mid-water
29 Jan 2008	D19	153	193	Mid-water
29 Jan 2008	D19	153	313	Bottom water



Exopolymers and their microbial producers (Ewert Sarmiento and Deming)

The Arctic winter environment provides an opportunity to explore some of the most extreme conditions of low temperature and high salinity that may be experienced by Earthly organisms. Winter sea ice, brines, frost flowers, and snow all present environments of interest to search for microorganisms adapted to low temperatures and/or high salinities. Microorganisms inhabiting some of these environments have been proposed to produce extracellular polymeric substances (EPS) as cryoprotectants. On this leg, a concerted effort was made to bring into culture microorganisms that may produce such substances.

Samples from a diversity of environments were cultured under various conditions of temperature and salinity, aiming to select for cold- and salt-adapted organisms. Among the environments sampled were: cores of first year ice (FYI), new ice (NI), brines collected from first year ice (B), frost flowers (FF), surface seawater (SSW) and sea water at different depths (SW). Sea ice samples were taken in collaboration with team 8.

A culture medium rich in complex organic substances was compared with a defined medium containing only one source of sugar, one source of amino acids and vitamins. Two salinities, 35 and 52, were also evaluated. Replicates of all inoculated media tubes were incubated throughout the leg at both –1.4°C and –7°C.

A new field method designed to select for organisms or substances with ice-affinity properties by circumferential freezing (CF) was also tested during this leg. This method consists of chilling a series of metal rods under sterile conditions in a –80°C freezer, then introducing the rods into the sample of interest in order to generate artificial ice. The process of ice generation is expected to cause the segregation of selected microbes into the ice sample, while others may be excluded from the ice, depending on their exterior properties. This method is partially based on the "cold finger apparatus" developed by Kuiper *et al.* (2003), which has been used to isolate cold-adapted microorganisms from soil samples (Wilson *et al.,* 2004).

To complement the culturing effort, parallel samples of the environments sampled were processed to measure dissolved and particulate EPS by the phenol–sulphuric acid method. Bacterial abundance will also be determined by epifluorescence microscopy.

Surface snow and frost flowers (all participants)

Taking advantage of the unique sampling opportunities offered by this leg, we added snow and frost flowers to our sampling plans. Snow samples were taken as early as possible after the ship was safely docked into a floe to minimize contamination from the ship (D17, D18, and D19). Prior to the ship entering floe D19, pristine snow was collected by helicopter landing. All snow samples were processed for analysis of bacterial abundance and diversity.

When seawater freezes, any impurities in the water are excluded from the ice as more water molecules stick together under freezing temperatures. Microbes and salts are known to be concentrated in the liquid that remains between ice crystals. By the same process, microbes are expected to be concentrated in the brine that forms frost flowers. Frost flowers were sampled starboard of the *Amundsen* after the ship had drifted for two days at station D17. Samples were processed for DNA (microbial diversity), EPS, and bacterial abundance, and used in culturing experiments. The melt water of ship-side frost flowers contained mm-size particles, some of which obviously resembled ship paint. This first sampling provided an opportunity to develop suitable sampling techniques, but given the contamination from the ship, we searched for newly formed frost flowers remote from the ship at station D19. On day two at floe D19, we visited an open lead about 300 m from the ship, much of which was growing new ice (0.5-inch thick). Two days later frost flowers had formed on top of an accessible new ice area. These newly formed frost flowers were sampled and processed as before. Microstructural analyses of individual crystals of the frost flowers were also conducted shipboard.

Photos showing the evolution of this lead from newly formed ice to fully formed frost flowers are presented below.

Other experiments (Ewert Sarmiento)

Two experiments were developed in collaboration with team 8 (contaminants). We are especially grateful to Monika Pucko, Wojciech Walkusz, Amanda Chaulk and Jeff Latonas for the help and training they provided.

Temporal evolution of an ice core during melting
When sea ice melts it releases to the underlying seawater both water molecules that had formed the solid phase of ice and salts and other molecules that had been trapped inside the brine channels and pockets. To approach the characteristics of this release, we joined team 8 in an experiment where first year ice cores were subjected to controlled melting.

Ice cores from station D19 stored inside clean plastic sleeves were hung in vertical position to allow dripping from the bottom of the plastic sleeve. The experiment set-up was at an air temperature of about 10–15° C to let them melt somewhat slowly. Meltwater from one of the cores was collected in a sterile bottle underlying the core (and sleaved to it with sterile foil). When the volume of the melt reached 1L, a sample was collected for salinity, bacterial counts and EPS measurements. Participants from team 8 collected samples for the measurement of HCH.

The experiment was replicated to measure with higher resolution the first 12 hours of the melting process and to include measurements of mercury concentration. In this second case, the meltwater was collected every 1.5 hours for salinity, bacterial counts and EPS measurements.

Mercury resistance
In order to select for microorganisms with potential mercury resistance, frost flower samples were cultured in 1/2x2216 marine broth under two conditions of salinity (35, 52) and increasing concentrations of mercury, from 0.5 to 4.0 ppt, and incubated at –1.4°C.

Table of samples collected during Leg 5B: new ice (NI), first year ice (FYI), brine (B), frost flowers (FF), snow, surface seawater (SSW), seawater at different depths (SW) and snow. Circumferential freezing experiments were conducted on selected samples (*). In collaboration with Monika Pucko and Wojciech Walkusz, from Team 2, melting core (MC) experiments were performed. Samples were processed for later analyses in the home laboratory of DNA content (DNA), lipid composition (lipids), environmental parameters (POC/PON, Chl *a*, SPM), bacterial abundance (DC) and bacterial cultures in liquid and solid media.

2.6. Team 8

PI: Gary Stern (DFO, Freshwater Institute)
Participants: Debbie Armstrong (University of Manitoba)
Amanda Chaulk (MSc student, University of Manitoba)
Jeff Latonas (MSc student, University of Manitoba)
Monika Pucko (PhD student, University of Manitoba)
Wojciech Walkusz (DFO, Freshwater Institute)
Jason Pavlich (chemistry teacher, USA)

General objective
The question this project hopes to answer is how climate variability in physical forcing and the biogeochemical response to this primary forcing will affect the cycling of the contaminants hexachlorocyclohexane (HCH) and mercury (Hg)/methyl mercury (MeHg). Ultimately, we propose to relate changes in delivery and biogeochemical cycling of these contaminants to their levels in fish, marine mammals and the people who consume these tissues as part of their traditional diets.

2.6.1. Organic contaminants

(Pucko, Walkusz and Pavlich)

Hexachlorocyclohexane (HCH)

Technical HCH is a mixture of several isomers, the most abundant being □-HCH (60-70%), □-HCH (5-12%) and □-HCH (10-15%). Technical HCH and pure □-HCH (lindane, pesticide active isomer) have been used for over 50 years and are now ubiquitous in water throughout the northern hemisphere with the highest levels found in the surface water layers near pack ice in the Arctic Ocean.

Technical HCH was banned or heavily restricted by China, the former Soviet Union and India between the mid-1980s and 1990. Concentrations of □-HCH in arctic air responded quickly to these large-scale usage changes and declined by an order of magnitude from the early 1980s to mid-1990s in steps that closely matched global usage and emission estimates. As a consequence, the direction of net gas exchange in arctic waters reversed from deposition in the 1980s to air-water equilibrium or volatilization in the mid-1990s.

The □-isomer is the prominent one in Arctic air, water, biota and soil, and moves northward via cold-condensation, a process whereby the contaminant evades into the atmosphere, drifts with atmospheric currents, and condenses in colder climates, where colder temperatures increasingly favour the water and extensive ice cover inhibits further evasion. Hence the contaminant accumulates disproportionately in the Arctic.

Water sampling

Seawater (4L) was collected from the rosette every 4-6 days. Where feasible, transects across water bodies were collected. In the lab, water was pumped through a glass-fiber filter followed by an ENV+ solid-phase extraction (SPE) cartridge using peristaltic pumps. Filters and cartridges were frozen and brought back to the Freshwater Institute for analysis. $^{18}\delta O$ were also collected at each site and depth where HCH samples were taken.

27-Jan-08	D19	10 25 50 100 150 200 250 bottom (306)

During the last water sampling (27 Jan 2008) water from each depth was taken for culturing bacteria and processed by Marcela Ewert Sarmiento (Jody Deming's team). Bacterial cultures from different depths will be used in an HCH EF/bacterial degradation experiment during Leg 7/8.

Air Sampling

The air sampler was set up on the bow of the ship on the starboard side along with each ice sampling. Samples were collected on a glass fiber filter and polyurethane foam (PUF) for analysis of organic contaminants. Air sample collection time ranged between 4 and 10 hours. Filters and PUFs were frozen at –20°C and shipped frozen back to the FWI for HCH contaminant analysis.

Biotic Sampling (HCH, mercury, stable isotopes)
The main purpose of this study is to link physical and biological processes to mercury levels in the food web and to target biomagnification and bioaccumulation of HCH and mercury with stable isotopes and fatty acids in the pelagic food web. Thus, all biological samples collected will be measured for HCHs, total mercury and MeHg along with stable isotopes to place organisms into their associated trophic levels.

Biological samples were collected every 5-6 days. Various zooplankton families were collected using the vertically towed Tucker net (mesh size 0.2 mm). Zooplankton was sorted into families, placed into plastic vials and Whirlpak bags and frozen until they can be analyzed for HCH, THg, MeHg, stable isotopes and fatty acids.

Ice sampling
Ice samples for concentration and enantiomeric composition of HCHs were collected. The samples for oxygen isotope composition ($\delta^{18}O$) and salinity were taken along with all ice samples. The ice samples were collected in collaboration with team 2; the ice microstructural and physical analyses were made on all of them (see team 2 cruise report). Ice cores were cut according to ice microstructure into 8-30 cm layers, melted (4-8L of water) and pumped through a glass-fiber filter followed by an ENV+ solid-phase extraction (SPE) cartridge using peristaltic pumps. Surface water (4L) was sampled along with every ice sampling using a Niskin bottle. The cartridges and GFFs were stored at –80°C and brought to the DFO (Winnipeg) for further chemical analysis.

Ice experiment

At D14 site we did an ice experiment lasting 5 days. We cored at the same site every 12 hours to determine whether there are temporal (short-term) changes in HCH concentration and enantiomeric composition in the sea ice. Ice cores (4) were cut into 4 sections based on ice microstructure. Along with each ice coring, the suck hole was drilled (~ 75-80 cm deep) and left capped for 12 hours prior to brine collection. Ice temperature and salinity profiles were obtained and surface water, snow, oxygen 18, salinity and air samples were collected along with each sampling.

Zooplankton experiment

Calanus hyperboreus AF (Adult Females) were cultured for 6 weeks in 3 ng/L of α-HCH at various EFs (0.25, 0.5 and 0.75). Water spiked with pure acetone was treated as a control. The aim of this experiment was to determine whether they would come to an equilibrium HCH concentration and enantiomeric composition with water and, if so, how long it would take. The more general question of the experiment was: can zooplankton transfer HCHs in the water column during their vertical migrations?

Calanus hyperboreus AF (Adult Female)

Roughly 25 organisms were kept in each 1L jar closed with a lid. Water for the experiment was taken from ~ 50 m above bottom and filtered through GFF filter followed by 2 XAD columns set in a row to obtain HCH-free sea water. To obtain the final HCH concentrations and EFs HCH-free water was spiked with (+) and (–) HCH solution in cyclohexane (1)/acetone (3). Jars with zooplankton were kept in –0.5 to –1.0 °C in darkness. Half of the water in each jar was changed every 4 days.

Three-four replicates of ~ 25 organisms cultured at various HCH concentration/EF were frozen at –20 °C every 7 days and taken back to Winnipeg for further analysis. During the experiment set up zooplankton sample was taken to check the initial HCH concentration/EF.

Throughout the experiment water samples were collected to check HCH concentrations/EF: 3 blanks of HCH-free water, 3 sets of water after zooplankton culture and 2 HCH-free water samples spiked with 3 ng/L of HCH, EF =0.5. Water samples were spiked with 10 µL of standard HCH solution, filtered through GFF filters followed by SPE cartridges, frozen at –80 °C and taken back to Winnipeg for further analysis.

Table 6. List of water samples collected throughout zooplankton experiment.

Date	Sample code
24-Dec-07	blank 1 – HCH-free water
27-Dec-07	HCH-free water spiked with 3ng/L of HCH (EF = 0.5)
03-Jan-08	water after 1 week of culture, 0 HCH
03-Jan-08	water after 1 week of culture, 0 HCH +A (acetone)
03-Jan-08	water after 1 week of culture, 3ng HCH/L, EF=0.75
03-Jan-08	water after 1 week of culture, 3ng HCH/L, EF=0.5

03-Jan-08 water after 1 week of culture, 3ng HCH/L, EF=0.25

17-Jan-08 blank 2 - HCH-free water

20-Jan-08 water after 3 weeks and 4 days of culture, 0 HCH
20-Jan-08 water after 3 weeks and 4 days of culture, 0 HCH + A (acetone)
20-Jan-08 water after 3 weeks and 4 days of culture, 3ng HCH/L, EF=0.75
20-Jan-08 water after 3 weeks and 4 days of culture, 3ng HCH/L, EF=0.5
20-Jan-08 water after 3 weeks and 4 days of culture, 3ng HCH/L, EF=0.25

25-Jan-08 blank 3 - HCH-free water

29-Jan-08 water after 5 weeks of culture, 0 HCH/0 HCH + A (acetone)
29-Jan-08 water after 5 weeks of culture, 3ng HCH/L, EF=0.75
29-Jan-08 water after 5 weeks of culture, 3ng HCH/L, EF=0.5
29-Jan-08 water after 5 weeks of culture, 3ng HCH/L, EF=0.25

Ice experiment 2

The aim of this experiment was to determine at which point during spring ice melt HCHs are released into surface water. At station D19, along with ice sampling, 5 unbroken ice cores (92 cm long) were collected (24-Jan-08) and immediately hung upright in the aft chemistry lab (air temperature = 13.50–17.98 °C). Melt water was collected in equal portions from all cores to give a total volume between 2.93 and 6.48 L. A temperature profile was done on one of the cores every 4 hours until it was no longer possible due to core shrinkage. Five portions of melt water were collected, spiked with 10 µL of standard HCH solution, filtered through GFF filters followed by SPE cartridges, frozen at –80°C and taken back to Winnipeg for further analysis. Sub-samples for oxygen 18 composition and salinity were taken from each melt water.

Table 7. List of samples collected throughout ice experiment 2.

Date	Duration of melt [hours]	Volume [L]	HCH sample ID
25-Jan-08	0.00-9.00	6.28	1st melt water
25-Jan-08	9.00-14.17	6.35	2nd melt water
25-Jan-08	14.17-20.00	6.48	3rd melt water
26-Jan-08	20.00-28.00	5.00	4th melt water
26-Jan-08	28.00-46.00	2.93	5th melt water

Cores melting for ice experiment 2.

T_{32cm}	0.79 °C

2.6.2. Mercury and Methyl Mercury

(Armstrong, Chaulk, Latonas)

Mercury (Hg), long been known as a neurotoxin, has emerged as a contaminant of great concern in the Arctic. Although global Hg emissions are declining, marine mammals in certain areas in the arctic have exhibited increasing Hg concentrations during the past two decades. Hg concentrations have been observed in liver of beluga whales from the Beaufort Sea area since 1982, peaking at 29.0 µg/g (wet wt., age corrected; 41.5 µg/g without age correction) in 2002, and remaining as high as 13.5 µg/g in 2002 (consumption guidelines for fish tissue are 0.5 µg/g). The biomagnification of Hg throughout the foodweb is well documented; however, the cyclical behavior of Hg and how abiotic Hg interacts with the foodweb are not well understood. We are also interested in oceanic and riverine inputs/exports of Hg into or out of specific geographical regions such as Hudson Bay.

During Leg 5 of the CFL Expedition, the mercury team onboard the CCGS *Amundsen* began their work to study the cycling of Hg in the Arctic. Hg exists in many forms, elemental mercury Hg(0), reactive gaseous mercury Hg^{2+}, particle bound mercury, organic mercury and dissolved inorganic mercury. Team 8 is attempting to measure and monitor these forms and the movement of each that develops in both the winter season and with the onset of spring. After polar sunrise and throughout the spring ice begins to break up and as a result of this, open leads are formed. This open water and the halogens that are emitted from it are believed to play an important role in the cycling of mercury in this environment. It is believed that atmospheric mercury in the form of gaseous elemental mercury undergoes oxidation to reactive gaseous mercury which can fall to the surface in the form Hg^{2+} or bind

to particles in the air, becoming particulate mercury. This atmospheric process is known as mercury depletion events (MDEs). Not only does the open water affect the atmospheric chemistry of mercury but also offers a route for direct deposit into the water column.

Sampling Activities

1. Water samples for profiles of total mercury and methyl mercury in the water column were taken from the rosette in the moonpool, with surface water sampled from the ice. This sampling method represents mercury movement with horizontal oceanic water mass transport. O^{18} samples were also taken with every mercury sample.

2. Atmospheric mercury systems were set up and partially running for gaseous elemental mercury GEM to measure the ambient levels in the atmosphere in this region and to indicate the onset of MDEs.

Tekran atmospheric mercury system on the foredeck of the ship.

3. Snow, brine and ice samples were taken to follow the movement of mercury and its forms through the snow/ice interface and the ice/brine interface. Both new (nilas) and old ice were sampled along with frost flowers where the opportunity presented itself. All ice was characterized with microstructure, temperature and salinity measurements. All coring activities coincided with the HCHs team and described above. At every station sac holes were dug for brine sampling the following morning. Surface snow grabs (triplicate) were a constant daily activity where time and weather permitted. A melt experiment was conducted at station D19 where the core was left to melt and sampled periodically in order to determine at which point mercury is released, a temperature profile was conducted simultaneously.

SNOW COLLECTION: D11, D12, D13, 5-day time series at each D14, D17, D19.

Frost flower sampling on the newly formed ice behind the ship.

New ice (nilas) sampling from the cage (Station D18a and D18b) during transit.

At the end of Leg 5 the contaminants team developed a 5 day recommended sampling plan to meet all the needs of the projects that have begun.

Contaminants 5 Day Sampling plan

Day 0 Site Setup

Setup site markers: choose site upwind and away from the current under the ship (ADCP); we use the zoo hole so make sure it matches this criteria Start Hg air instruments		
Day 1	Coring Day	
Check Hg air instruments - daily checks completed HCHs air started just before you core, turned off after ~ 5 hours		
Ice coring:	Hg x2 HCHs x7 + 1 for micro (ice 1m thick - 8 cores; if 50 cm thick then 10 cores) 4L surface water taken from core hole for HCHs -before you filter take a sample for salinity and O18 - give salinity sample to Amanda/Pascale to be measured bottoms for Alexis - #? -coordinate with Gosselin/Poulin/Michel group temperature of core salinity of core microstructure started	
Day 2	Brine/HCHs Day	
Check Hg air instruments - daily checks completed		
Ice sampling:	snow for Hg brine for Hg frost flowers for Hg (new formation time series) and for HCHs if there is a lot	
HCHs moonpool	profile: surface (after core taken), 10m, 25m, 50m, 100m, 150m, 200m, 300m, bottom with O18 zoo picking	(done every 5 days) (for HCHs)
Day 3	Water Day	
Check Hg air instruments - daily checks completed		
ice core work:	microstructure done: ice cut and scraped and left to melt	
Hg moonpool	on nutrients rosette: collect depth profile (duplicates at least) with O18 THg with nutrient depths, 10m, 20m, 30m, 40m, (or chl max) 50m, 60m, 80m, 100m, 120m, 140m, 160m, 180m,	

	200m, 250m, 300m, 500m, 750m, 1000m, bottom plus blanks MeHg: 10m, chl max, 50m, 100m, 150m, 500m, 1000m, bottom, blanks
minimum plan:	sample different water masses (varying temp, salinity, chl. Max, surface and bottom): 1m, 10m, chl max, 50m, 100m, bottom, blks)
Hg on ice	same day as the rosette: collect surface profile from zooplankton hole (before they do a net tow): with O18 THg and MeHg: 7m, 5m, 3m, 1m plus blanks (duplicates) snow sampling
Day 4	HCH Filter Day
Check Hg air instruments - daily checks completed	
Lab Work	microstructure finished sample decanting run THg (wait until all ice is melted)
HCHs	ice filtering- before you filter take a sample for salinity and O18 - give salinity sample to Amanda/Pascale to be measured
Hg Ice Work	snow sampling
New Ice ?	Cores if possible
snow pits	good after snowfall
Day 5	Extra Day/New Sites
Check Hg air instruments - daily checks completed	
Lab Work	run MeHg (every 2 or 3 stations)
Hg Ice Work	snow sampling
New Ice?	brine?

In conclusion, this leg proved to be quite challenging for the mercury team (whose problems will all be fixed shortly). Be sure you have fun, do good science and smile, the sun has risen!

2. Team reports

2.1. Team 1

2.1.1. CTD/Rosette

PI: Yves Gratton
Participants: Clément Clerc, Marie-Emmanuelle Rail (INRS-ETE, 490, Rue de la Couronne, Québec)

Objectives
Description of water masses and general circulation over a year in Beaufort Sea and Amundsen Gulf.

Materials
Physical parameters were recorded using a ship mounted RDInstruments Ocean Surveyor ADCP (150kHz), and a rosette frame equipped with 24 bottles of 12 L and the following sensors:

Table 1: Sensors used on the Rosette.

Photo	Item	Manufacturer	Type & Properties	Serial Number
	CTD	SeaBird	SBE-911 Sampling rate : 24 Hz	
	Temperature	SeaBird	SBE 3plus Range: -5°C to + 35°C Accuracy: 0.001	4204
	Pressure	SeaBird	Accuracy: 0.015% of full range	90584
	Conductivity	SeaBird	SBE 4C Range: 0 to 7 S/m Accuracy: 0.0003	2696

	Fluorometer	Sea Point		2465
	Transmissometer	WetLab	Path length: 25 cm	CST-558DR
	Altimeter	Benthos		1061

Method

For the whole leg, because of heavy ice conditions, the rosette was deployed from the Moonpool. CTD or Rosette casts were usually performed two times a day at 7a.m. and 7pm. Four times, we did a 13 hours non-stop CTD sampling. Water was sampled according to each team requests. Here are examples of usual depths collected by them.

- *Nutrients* (Team 7; PI: Jean-Éric Tremblay): salinity of 33.1, 10, 20, 30, 40, 50, 60, 80, 100, 120, 140, 160, 180, 200, 250, 300 and every 100 m up to the bottom.
- *DIC* (Team 6; PI: Lisa Miller): salinity of 33.1, 10, 20, 30, 40, 50, 60, 80, 100, 120, 140, 160, 180, 200, 250, 300 and every 100 m up to the bottom.
- *Contaminants* (Team 8; PI: Gary Stern): 10, 25, 50, 100, 200 m and bottom.
- *Microbes* (Team 7; PIs: Carlos Pedros and Roxanne Maranger):
- *pH/alkanilitys* (Team 6; PI: Alfonso Mucci): salinity of 33.1, 10, 20, 30, 40, 50, 60, 80, 100, 120, 140, 160, 180, 200, 250, 300 and every 100 m up to the bottom.

Sampling field

We focus on the Amundsen Gulf.

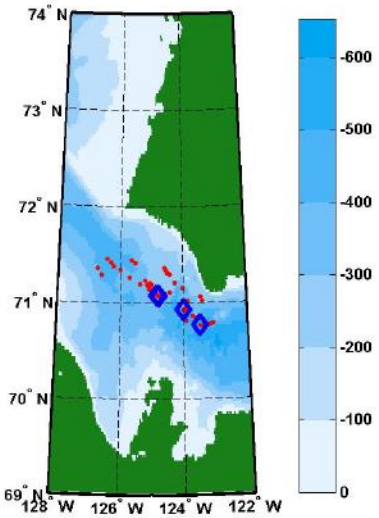

Figure 1: Positions of Rosette casts are shown as red dots and stations of 13 hours sampling are blue diamonds.

Probes calibration

Salinity: Samples were taken on many casts with small bottles of 200 mL. They were analysed with an autosal GuildLine, model 8400B. Its range goes from 0.005 to 42 and its accuracy is <0.002. The results were satisfying. The difference in between the salinity probe recordings and the samples was around 0.033.

Oxygen: Oxygen sensor calibration was performed using Winkler's method and a Mettler Toledo titration machine. Reagent Blanks were performed once, results show that chemicals are still good (m<4). We sampled oxygen on eight casts. Each time, we choose five depths of different oxygen concentration and sampled it three times. Results were really goods, the probe recordings and the samples were always pretty similar.

pH: Tests were done using two buffers. The sensor is quite stable. Results are as follow:
Buffer 4.01 gave 4.09
Buffer 7.00 gave 7.45
Sea water is usually around pH=8, we can expect pH data to be a little over estimated.

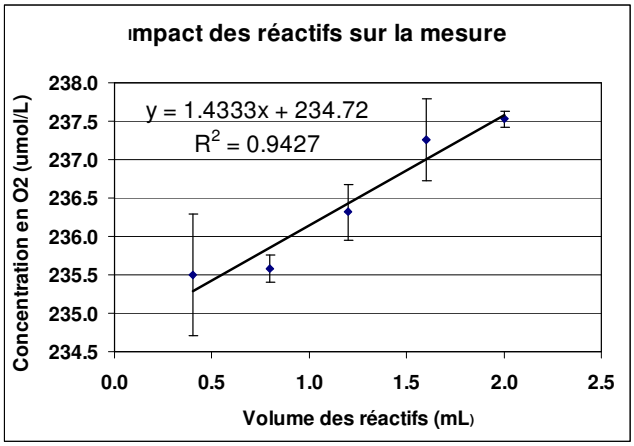

Figure 2: Reagents Blanks (m=1.4333).

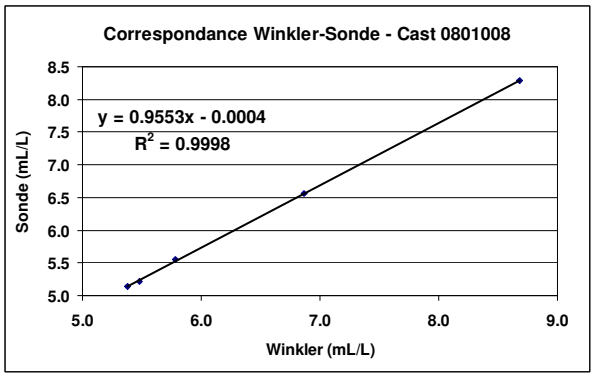

Figure 4: Relation between samples and probe recordings during cast #008 (m=0.955).

Problems

- **Sensors**
  No real problem. Only some water infiltration once in a while.
- **Bottles**
  Some bottles are leaking, which is a problem that persists since a few legs. There is also bottle number 5 that was not closing all the time.
- **Deck material (winch, A-frame, etc.)**
  The cable guides broke a few times which is also a recurring problem. The winch got no problem.
- **ADCP :** It's something difficult to get data on the whole water column. We were really carefull and we try to remove ice from under ship each time we took position so I'm not sure why we don't get data on the whole water column. Frazil?

Available data

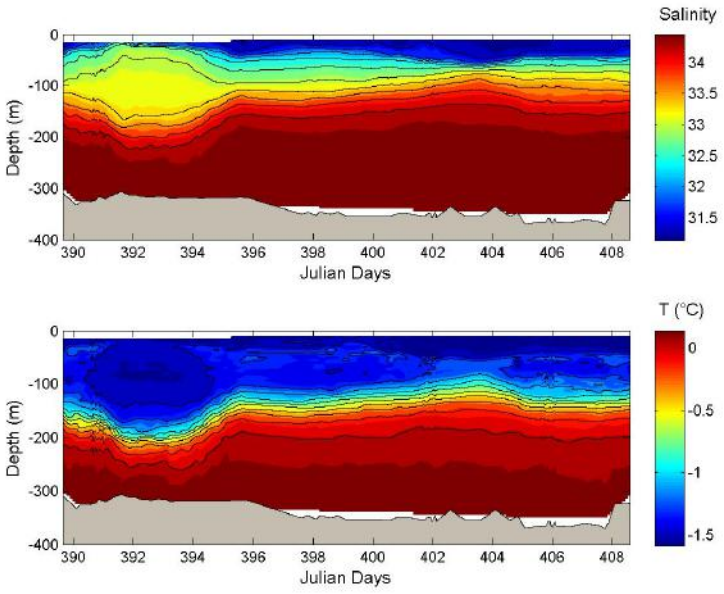
All information concerning the Rosette casts are summarized in the CTD Logbook. It includes cast and station numbers, date and time of sampling in UTC, latitude and longitude, bottom and cast depth, comments concerning the cast and its name. A Rosette sheet was also created for every single cast. It includes the same information than the CTD Logbook plus the bottle distribution among every sampling team. The weather information is written in every Rosette Log as well as in a meteorological logbook. For every cast, data recorded at the moment of bottle closure were averaged and recorded in the so-called 'bottle files'. Averaged data are those recorded between 3 seconds before bottle closure and 7 seconds after it. It includes the bottle position, time and date, pressure, temperature, salinity, transmissivity, chlorophyll, oxygen, irradiance and pH measurements. All those files are available on the 'Shares'.

- Rosette sheets and the CTD logbook : Shares\Leg6\Rosette\logs
- Bottles files : Shares\Leg6\Rosette\btl
- Plots of every cast including salinity, temperature, oxygen, transmissometer, nutrients, fluorometer and irradiance : Shares\Leg6\Rosette\plots

Between January 31st, 2008 and March 12th, 2008 137 casts were performed.

Preliminary Results

This time serie represented data recorded on station D19 from the end of Leg 5 to the second week of Leg 6. We may have recorded an eddy carrying its own water masses by the end of January.



2.2. Team 2

2.2.1. Ice dynamics

PI: David Barber
Participants: Matthew Asplin, Lauren Candlish, Pascale Collin, Klaus Hochheim (6A only), Dustin Isleifson (6B Only), Dan Leitch (6A only)

General Ice Conditions
Leg 6 started with the ship stationed in a long-term drift station within medium first-year ice (FYI) where the ice thicknesses ranged from 90 to 100 cm. Severe southeasterly winds created significant ice divergence and motion which consequently forced us to move from our station (D19) on February 13th. We examined ice at various stages of formation, from open water up to greater than one metre-thick ice. The prolonged southeasterly winds led to the break-up of nearly the entire Amundsen Gulf ice sheet, thus impacting the formation of the fast ice bridge between Nelson Head and Cape Parry.

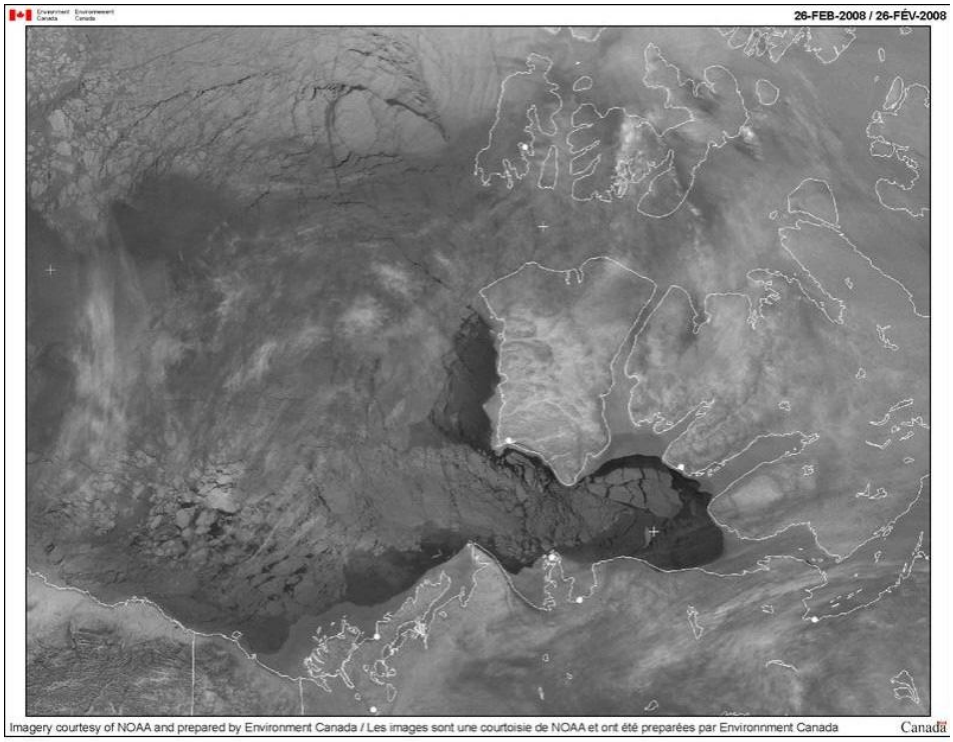


Figure 1. AVHRR image from February 26, 2008.

Physical Sampling
The Team 2 CFL ice raid program continued throughout Leg 6 following the protocol that was previously established in Leg 5. We have termed this sampling "Drift Mode Sampling." The goal is to obtain physical and microstructure measurements of the snow and sea ice, and for twice-daily sampling to occur at the same time as the passage of a train of arctic monitoring satellites at 9:30 and 3:30pm. We continued the drift mode sampling protocol, protecting our EM scanning site with a fence, and performing twice-daily sampling in areas indicative of the area being scanned. There were several chances to visit the flaw lead and consequently examine thin and newly forming ice and therefore samples were taken on an opportunistic basis to optimize our data collection.

The ice surface condition was recorded and site photos were taken. The nature of ice coring and snow pit work depended on how many days we had been at that site, but in general we followed the sampling protocol outlined in Table 1.

Table 1. Drift Station Physical Sampling Protocol.

DAY	ICE (AM)	SNOW (AM)	ICE (PM, TOP 40 CM ONLY)	SNOW (PM)
Day 1	T, Sal, VMS, D	T, Cap, SGA, D, depth	T, Sal	T, Cap, SGA, D, depth
Day 2	T, Sal	T, Cap, SGA, D, depth	T, Sal	T, Cap, SGA, D, depth
Day 3	T, Sal, HMS, D	T, Cap, SGA, D, depth	T, Sal	T, Cap, SGA, D, depth
Day 4	T, Sal	T, Cap, SGA, D, depth	T, Sal	T, Cap, SGA, D, depth
Day 5	T, Sal	T, Cap, SGA, D, depth	T, Sal	T, Cap, SGA, D, depth
Day 6	T, Sal	T, Cap, SGA, D, depth	T, Sal	T, Cap, SGA, D, depth
Day 7	T, Sal	T, Cap, SGA, D, depth	T, Sal	T, Cap, SGA, D, depth
Week 2 at site	Repeat from day 1	Repeat from day 1	Repeat from day 1	Repeat from day 1

Ice: T = temperature profile (T = core temperature profile, Sal = core for Salinity, VMS = core for vertical microstructure, D = core for density, HMS = core for horizontal microstructure
Snow Pits: T = temperature profile, Cap = capacitance plate, SGA = snow grain analysis, D = density

In summary, we took ice cores twice per day for salinity and temperature profiles, with the 3:30 pm ice cores limited to the top 40 cm. A core was taken for vertical microstructure on day 1, and for horizontal microstructure on day 4. We intended to take an additional core for ice density; however, due to equipment problems with the bandsaw we had no means to make accurate cuts and therefore did not perform this task. We also performed a twice-daily snow pit measurement according to our standard procedure. This includes temperature profiles, salinity profiles, capacitance plate measurements, and snow grain photos.

Figure 2. Typical snowpit measurement procedure.

Table 2. Ice Sampling Summary

DATE	STATION	SNOW	ICE TYPE	ICE MICRO
03-Feb-08 to 11-Feb-08	2008D19	Variable (4 – 18 cm)	First year ice (105 cm)	Vertical & Horizontal
17-Feb-08	2008D21	3 cm	First year ice (69 cm)	n/a
18-Feb-08 to 19-Feb-08	2008D22	Variable 2.5 – 7 cm	First year ice (69 – 97 cm)	n/a
24-Feb-08 to 29-Feb-08	2008D26	Uniform (3 – 5 cm)	First year ice (110 cm)	Vertical & Horizontal
01-Mar-08	2008D27	0	Thin FYI (16 cm)	No
01-Mar-08 & 03-Mar-08	2008D28	0	Thin FYI (16.5 cm & 9 cm)	Vertical
05-Mar-08 to 08-Mar-08	2008D29	Main (9 cm) Drift (36 cm)	First year ice (120 cm)	Vertical & Horizontal
09-Mar-08	2008D30	0	New ice (from open water up to 2 cm)	No
10-Mar-08	2008D29 (returned)	Uniform (4 cm)	First year ice (130 cm)	No

At the end of Leg 6 we returned to Station 2008D29. However, the ship was positioned in a different section of the ice where the snow had not been distributed in large drifts. The naming convention requires this station to remain as 2008D29; however, it should be noted that the snowpack is different, whereas the ice floe is the same.

Ship Based EM Measurements

EM measurements were conducted throughout Leg 6 in order to observe the interaction of electromagnetic radiation with various ice conditions. The collected data will be used in electromagnetic modeling studies and for calibration of satellite remote sensing data. The results of this study will allow for us to improve our knowledge of the temporal evolution of sea ice physical, thermodynamic, and electrical properties during the winter ice growth period. We had an exciting opportunity to observe sea ice grow from open water up to 2 cm thick in a large flaw lead at Station 2008D30.

Figure 3. New ice forming in the open lead of Station 2008D30.

Scatterometer
A fully polarimetric scatterometer system was operated at each station stop. The height of the instrument above the surface has been regularly measured and maintained in the operations log. Measurements from the ship were conducted with a sweep from -30° to 30° in the azimuth, requiring the 0° reference at a perpendicular line to the ship side. The variation in elevation was measured with sweeps in the elevation at 5° increments on the range 20° to 60°. An infrared transducer (Everest, 4000L) was mounted on a rail near the scatterometer.

At the beginning of Leg 5B, we had noticed that sometimes the noise floor of the system would rise and therefore some of the radar returns would be lost in the noise and corrupted. The occurrence of this problem has significantly reduced in frequency during Leg 6. We have communicated with the manufacturer and they have assured us that no field maintenance can be performed to further improve the problem; however, the data is still usable. At this point in time, our course of action is to continue to collect data and we will deal with the major increase in post-processing time and data filtering in our final analysis back at the University of Manitoba.

It should be noted that a data collection flaw was discovered during the leg with the IR transducer. The data logger did not have enough memory to log more than 3 hours of data, and the attached storage module was not configured to log at all! This was rectified by reduction of the sampling resolution to once per minute and the eventual employment of a 16MB storage module – the existing storage module was only 512KB.

Ship-Based Radiometer (SBR)
Dual polarized radiometers operating at 37 GHz and 89 GHz with a 6° beamwidth were mounted about 12 m above the sea surface on the port side of the ship. The SBR conducted twice daily scans to correspond with our physical sampling program. The system was operated in a scan mode, changing the incident angle from 30° to 150° using 5° steps. During transit, the radiometers were kept at an incident angle of 55°. A network camera was used to monitor the surface conditions at a sampling rate of 10 s while in transit. The settings have not been changed otherwise. In addition, a hand-held camera is used at each site to provide more information on the surface conditions.

Laser Profiler
The laser profiler was disassembled and put in storage during Leg 5, and thus was not operated during Leg 6.

Skippyboat
The purpose of the skippyboat is to allow us to investigate several sites using the ship based EM equipment, and still return to the sites to perform physical sampling. The skippyboat was winterized at the end of Leg 4, and thus was not deployed during Leg 6. It should be noted that the skippyboat cover was destroyed by intense 50 knot winds, and the skippyboat is now exposed to the elements.

Coloured Dissolved Organic Matter (CDOM), Fluorescence of Dissolved Organic Matter (FDOM), Salinity and Oxygen Isotope ($\delta^{18}O$)

Dissolved organic matter (DOM) plays a major role in the ocean as carbon and energy sources for the microbial food web, and for consumers at higher trophic levels that feed on microbes or on DOM directly. The coloured fraction of this dissolved organic matter is a complex pool of autochthonous materials, derived from in situ photosynthetic activity and processed microbially, and allochthonous materials, that are rich in humic substances and largely derived from terrestrial environments.

This coloured dissolved organic matter (CDOM) is photochemically active and also influences the spectral underwater regime that in turn affects primary production. The composition and reactivity of CDOM in aquatic ecosystems are still poorly understood. The sources and dynamics of DOM are of special interest in the coastal Arctic Ocean. These environments receive inputs of freshwater from large rivers that drain arctic tundra and peatlands as well as subarctic boreal forest. To increase the understanding of this tracer we are coupling the sampling with $\delta^{18}O$ which is a conservative tracer of freshwater masses. It has been estimated that more than 25% of the world's soil carbon lies in these catchments, and there is concern about how ongoing climate change may mobilize these stocks and transport them to arctic seas. The carbon derived from arctic rivers appears to be a major source of terrigenous DOM to the deep ocean, and changes in the magnitude and composition of this material therefore have broader oceanographic implications.

Global circulation models predict that the arctic basin will experience greater and more rapid warming than elsewhere over the course of this century, and there is increasing evidence that global climate change has already begun to have significant impacts on permafrost degradation and terrestrial vegetation dynamics at high northern latitudes.

Water was collected onboard using the rosette from the moonpool. The ice was collected at stations D22 (see Table 3). The water was collected at 0 m, 5 m, 12 m, 25 m, 50 m, 100 m and 250 m on contaminant (THg) casts. The surface samples were always collected using a niskin bottle from the ice at 0 m and 5 m. $\delta^{18}O$ was collected by Team 5 for each station each depth.

The station D22 was selected for CDOM and FDOM in ice. $\delta^{18}O$ and salinity has been collected as well. Physical properties of sea ice have been noted and vertical microstructure analysis has been processed.

Due to problems with the spectrophotometer Cary 50, the CDOM samples has been store at 4°C and measurements of CDOM will be completed at University of Manitoba. Unfiltrated DOC sample was collected at station D27 to cover the different water layer composing the water column at depth surface, 100 m and 250 m. DOC as been stored frozen at -20°C until further analysis can be performed.

Preliminary Results:
CDOM and FDOM analysis will be performed after the cruise in laboratories at the University of Manitoba. Stable isotope analysis of water and ice samples will be analyze outside of the university.

Table 3. CDOM and FDOM sample locations.

Date (mm-dd-yyyy)	Station (#)	Cast (#)

01-03-2008	D27	103

Please note that station 19D 02-11-2008 has been process from the same bottle as that of Team 6 (Carlos Pedros from Spain) to analyze organic compounds and functional and structural bacterial diversity.

Atmospheric Sampling Program
The purpose of the atmospheric sampling program is to monitor cloud cover and cloud properties, upper level and boundary layer winds, temperature, and humidity.

All-Sky Camera
The all-sky camera system is used to take pictures of sky in order that percentage and type of cloud cover may be determined throughout the cruise. The all-sky camera was non-functional upon our

arrival onboard the ship due to the destruction of the hemispheric dome during Leg 5B. Two new domes were brought to the ship. We were successfully able to heat the dome to keep it frost-free by installing a dense network of heating wire and an ambient heat source inside the dome. Furthermore, the lens hole was enlarged on the webcam enclosure. The camera-system is now fully functional and taking pictures at a 15-minute interval; however, sun glare will continue to be a problem until an appropriate lens can be installed at the start of Leg 7.

Ceilometer

The ceilometer is used to measure the height of the cloud layers above the ship. The ceilometer was fully functional throughout all of Leg 6. Routine maintenance and backup was performed at regular intervals.

Profiling Radiometer

The profiling radiometer is used to measure the temperature, relative humidity, and pressure within the atmosphere. The profiling radiometer has been running smoothly, with only occasional crashing of the interface software on the laptop due to a memory leak. Data collection was not affected. A liquid nitrogen calibration was conducted on February 26, and will be one more time during CFL during Leg 8. The instrument has collected wonderful data on various different atmospheric circulation patterns including highs, cyclones, weak low-pressure depressions, and strong geostrophic flow situations.

Radiosondes (weather balloons)

There were 18 balloon launches during Leg 6. Balloon launches were conducted to correspond mainly with low-pressure depressions and cyclones, but a small number profiled high pressure systems, and low-level inversions. The balloon tether system, constructed by our Russian team 2 collaborators during Leg 5, was improved and employed on several occasions in an attempt to collect time-series data at approximately 250m above the ground. Battery charge life, and changing wind conditions prevented us from collecting time series greater than 4 hours. Balloons used for tethered experiments were generally re-used immediately after as regular profiling balloons due to no storage location for the balloons. Furthermore, our limited helium supply precluded us from re-inflating the same balloon repeatedly. A radiosonde was also successfully attached to a kite, courtesy of Doug Barber.

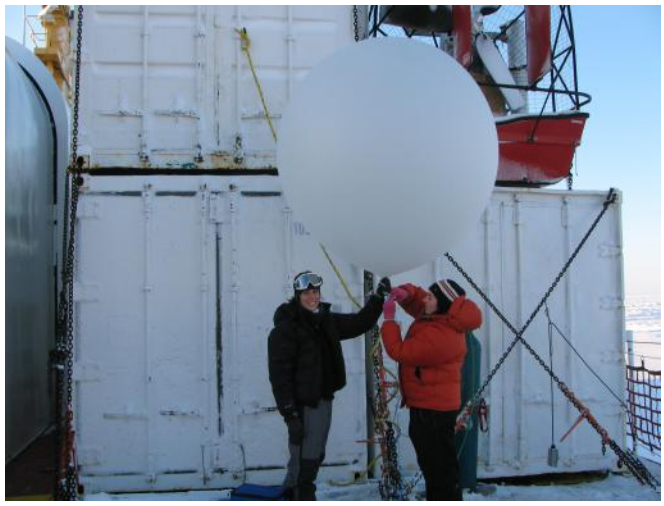

Figure 4. Attaching a radiosonde to a balloon for an atmospheric profile.

Laser Precipitation Gauge

This instrument was fully functional throughout Leg 6. The instrument continues to run as per normal, and all data has been downloaded and archived.

Ice Motion Beacons
Ice beacon deployment was initially delayed by our "Jiffy" auger having died during Leg 5. Upon arrival of a new auger at the start of Leg 6B, we were able to begin to deploy ice beacons during Leg 6, and future deployments will be at approximately 2 week intervals or as significant opportunities arise (MYI floes).

Table 4: Ice motion beacon deployments.

Beacon ID	Date Deployed	Location Deployed	Status
20610	Feb 23	D23	ACTIVE
13330	Feb 24	D26	ACTIVE
14310	Feb 27	By Heli near D26	ACTIVE
19300	Mar 6	Near D29	ACTIVE

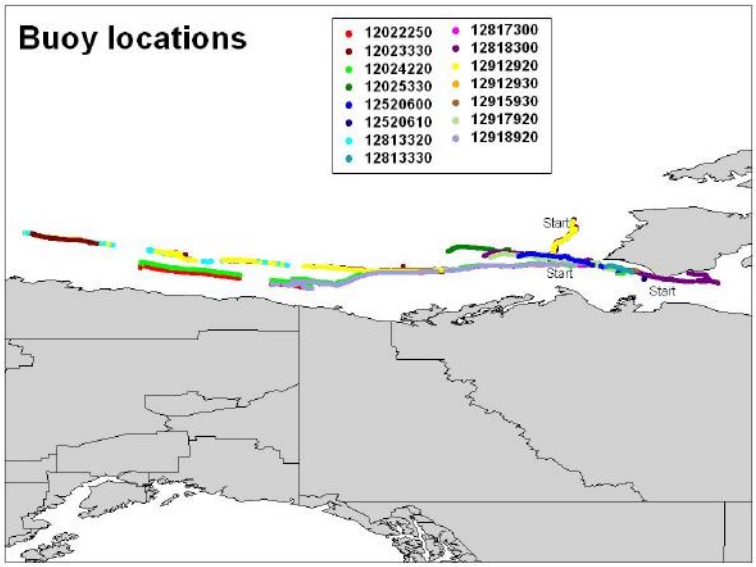

Figure 5. Ice motion buoy locations as of February 25, 2008.

Met-ocean MOBS Buoys
Two improved MOBS buoys were received, but could not be operated due to the direction finder having not been shipped up. The buoys are presently stored near and inside the benthic lab.

Met-ocean POPS Buoy
No POPS buoys were on the ship during Leg 6.

AVOS (Environment Canada MetObs System)
This system was operating normally, with the exception of a few glitches in data transmission that were worked out by the ship's electronics officer.

Recommendations
In general, the data collection is proceeding as planned with no major issues that have not been resolved. As time progresses and we enter the winter it is imperative that all exposed instruments must be free of frost buildup and must be maintained at correct operating temperatures. We also recommend close monitoring of the usage of the core barrels as we became dangerously short on pins.

The cold lab temperature was regularly maintained throughout Leg 6. We were advised by Frederic (PI Tison) to reduce the temperature of the cold room to below -23C, as this is a critical temperature at which brine drainage can occur while processing horizontal microstructure samples. We recommend continued defrosting of the lab every 10 days to minimize frost build-up and to keep the

temperature at or below -23C. We also employed usage of the microtome for making very clean shaven surfaces on the microstructure work. We also found that it can be helpful to flip the ice on the plate and shave the bottom so that the sample would be free of air bubbles.

2.3. Team 4

2.3.1. Zooplankton and fish Acoustic

PI: Louis Fortier
Participants: Anaïs Aubert (U. Laval), Hélen Cloutier (U. Laval), Gérald Darnis (U. Laval), Louis Létourneau (U. Laval), and Steve Gagné (electronic technician from U Laval)
Written by: Gérald Darnis, Hélen Cloutier, Anaïs Aubert and Louis Létourneau

Introduction

The fragmented, thin, and often absent ice cover in the flaw lead allows solar radiation to reach the surface layer of the ocean where it triggers photosynthesis by microscopic algae. Team 4, Pelagic and Benthic Food Web, will investigate how and to what extent the microalgae growing in the flaw lead are exploited by animals living in the plankton (the zooplankton) and on the sea floor (the benthos). Our simple hypothesis is that, relative to adjacent ice-covered regions, enhanced algal production in the flaw lead translates into biological hot spots where higher zooplankton and benthos abundances prevail. We will also investigate how the Arctic cod, a central species in the Arctic food web, uses the flaw lead for feeding, overwintering, reproduction, and as a nursery ground for their young stages (http://www.ipy-cfl.ca/page1/page1.html)

General objectives

The achievements of the members of our team during the previous leg 5 served as an example to build the sampling program of CFL leg 6. Thus the general objective of our team during this leg-6 CFL was again to collect indices of the ecosystem biological production -essentially the water column secondary production- in winter (February-March). Our sampling program was designed in the continuity of the overarching goal of ArcticNet project 1.4 led by Dr. J.-É. Tremblay (U. Laval) 'Marine productivity and sustained exploitation of emerging fisheries' which is to assess the impact of sea-ice cover reduction and increasing sea temperatures on biological productivity, fisheries resources and marine mammal populations of the coastal Canadian Arctic. Since October 18th, date the CFL program started, we focus on how the physical processes moderate biogeochemical processes within the changing northern flaw lead ecosystem nearby Banks Island (Beaufort Sea). Our multidisciplinary ArcticNet-CFL team is strongly linked with Team 7 (Carbon Fluxes – Tremblay) of the CFL program. For this leg-6 of CFL, sampling efforts were concentrated on the pelagic secondary producers.

The primary objectives of our team during CFL-6 were:

1- To assess zooplankton / fish abundance and diversity by using various plankton nets.
2- To track zooplankton / fish biomass and distribution with the EK60 Echosounder.

Our secondary field objectives were to collect and use the zooplankton sample for:

1- The cycling of contaminants in zooplankton (G. Stern, U. Manitoba)
2- Identification of the sources and pathways of omega-3 in the arctic marine food chain (J. Michaud, E. Dewaily and L. Fortier, U. Laval). This project linked to the CFL-URSUK program and the ArcticNet theme 1.5, focussing on the importance of omega-3 fatty acid in the traditional diet of Inuit communities.
3- Assessment of the biomass and respiration rates of the zooplankton community by the Electron Transfer System (ETS) activity at chosen stations (G. Darnis and L. Fortier).

4- Stable isotope analysis on the food web structure and carbon fluxes; this is a joint project between Team 4 and 7 of CFL (A. Forest, L. Fortier, J-E. Tremblay)
5- Copepod *in-situ* egg production (EPr) and gonad maturation of *Calanus hyperboreus* and *Metridia longa* (M. Ringuette, G. Darnis, L. Fortier)

Sampling program

Leg-6 sampling program was oriented towards ice work, when the ship was stationary on an ice flow for periods of time varying from 1 day to a week. Vertical sampling of the water column from the ice, initiated during the previous leg, was continued as well as the usual moon pool zooplankton sampling activities. We added a 60-0m ice tow to the usual 10-0 and 250-0m vertical tows to augment our sampling effort to catch Arctic Cod. Furthermore, building on a previous unintended collection of fish in short term sediment traps, we also deployed for 24-hour periods a line holding 3 traps in the ice hole serving for net sampling.

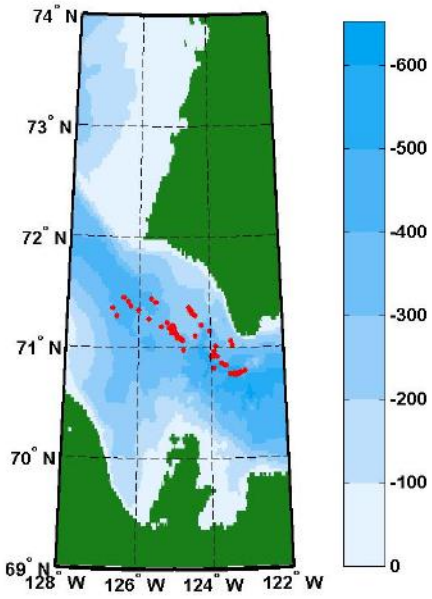

Fig 1: Locations of CFL leg 6 drifting stations.

1) Sampling gear and events

a) 1-m^2 Square net. Frame rigged with 1 square m^2 opening net (1 x 200, µm mesh), out-rigged with a 10 cm diameter net (50 µm) and equipped with a TSK flowmeter (Figure 1a). This net is used for integrated water column sampling that is summarized in table 1. When deploying, downward winch speed was <40 m/min to avoid mixing of the nets, and upward winch speed was 30m/min. To obtain quantitative tow (i.e. for taxonomy and abundance estimates), the content of the 200 µm (TSK) and the 50 µm mesh-net were preserved in formaldehyde (Fortier). Qualitative tows (i.e. 'live tows') were also performed to obtain animals for contaminants, lipids, EPr and/or ETS studies.

b) Hydrobios. Multi-depth plankton sampler (Figure 2b) equipped with nine 200 µm-mesh nets (opening 0.5 m^2). This was allowing for depth specific sampling of the water column. The *Hydrobios* is also equipped with a CTD to record water column properties while collecting biological samples. When deploying, downward winch speeds was 40m/min and the speed up was 30m/min. At most casts, the net collection was preserved in formaldehyde for taxonomic analysis but for some casts, the content of each net was divided: 50% for taxonomy (4% buffered formaldehyde) 25% for biomass estimates and 25% for ETS analysis (Table 2). The Hydrobios flowmeters appeared again to be

functioning perfectly after the troubles of leg 3 and 4. On one occasion, the Hydrobios hit the sea floor due to a wrong reading of the ship's echosounder. From then on, it was decided to check also the EK 60 when depths given by the bridge seemed doubtful. There was one incident in which the cable guide was damaged and needed a one-day repair. This prevented the deployment of the Hydrobios for one morning. A 24-hour Hydrobios sampling involving 4-hour intervals deployments was made during the leg. The targeted date for this sampling event was close to mid-leg but continual repositioning of the ship due to heavy drifting postponed this to the end of the second last week of the leg.

c) Ring net. A 1m diameter ring net equipped with a 200 □m mesh net and out-rigged with 10 cm diameter net (50 µm) and a flowmeter. This net was deployed three times per cast from a hole on the ice at proximity of the ship but at a site not influenced by its presence. Ice zooplankton sampling activities are summarized in table 3. A RBR CTD was always added to the net frame. At each station cast, the first haul was from 10 m to the surface and the second haul from a maximum of 270 m to the surface. Very soon after the start of the leg, it was decided to perform a last tow from 60 m to the surface to augment the sampling effort to collect Arctic cod larvae and juveniles. The net was lowered manually to the desired depth and pulled manually for the 10 m haul and using a snow mobile for the deep haul during the first cast. After many snow mobile breakdowns, we were asked to use the four wheeler to tow the nets. This engine proved to be better for the purpose as it provides more grip on the ice than the snow mobiles. On two occasions, the 50 µm

Overall, 139 sampling events occurred and 93 of the samples obtained were preserved for taxonomy, and the remainder, the 'live tows', were used for further analysis and laboratory experiments as described above. Samples for lipid and stable isotope analysis were placed in cryovials and stored at -80˚C. Samples for contaminants were sorted and preserved by Gary Stern's team

Laboratory analysis

1) Egg production rate experiments

Copepod *in-situ* egg production and gonad maturation (after Niehoff 1998) were monitored by incubating large calanoid species females at 0°C, thus at a similar temperature they experience at depth. The presumed non-reproducing *Calanus glacialis* was monitored weekly during the leg in order to verify and confirm its non-reproductive state. *Metridia longa* and *Calanus hyperboreus* egg production was measured approximately every 5 or 6 days. *Metridia longa* did not produce any eggs

but some females started to develop eggs and were close to spawning although gonadic index remains constantly low for the population. By the start of February, the entire population of female *C. hyperboreus* were having eggs in vitellogenesis, a sign that reproduction of the species was fully on. Measurements of daily egg production rates varied between 19 and 51 eggs f^{-1} d^{-1}. Some spent females start to appear in the live samples. On several occasions, eggs were sampled for dry weight measurements. Approximately 200 eggs were put to dry on a pre weighed GF/F filter that will be weighed again on a microbalance at Laval University.

Harsh winter conditions always provide difficulties in studying winter Arctic organisms. Because of this constraint, the metrics on the reproduction of *C. hyperboreus* is currently poorly documented. In order to measure the total production of *C. hyperboreus,* 50 immature females have been placed in filtered sea water during leg 5 and their egg production monitored daily. Eggs produced were then used to measure the hatching rates for different eggs buoyancies (sinking vs. floating). By the end of April we hope to get total reproductive output and the fate of this production. At this stage of the season, already 13 of the 50 females have spawned more than 1000 eggs. The record is presently held by female number 41 with a total of 1750 eggs spawned. Finally an experiment has been initiated to test the hypothesis arguing that *Metridia longa* can feed on *C. hyperboreus* eggs. (Conover & Huntley 1991). The question here is if they simply feed on these eggs or if they use this consumption to fuel an early reproduction, before the onset of the algal production. Thirty females are fed every second day with a known number of freshly laid *C. hyperboreus* eggs. On the second day, the remaining eggs are counted and removed before providing new ones. Gonadic stages of *M. longa* were recorded weekly.

2) Biomass and Transfer System (ETS) activity

On six occasions, corresponding to four stations (Table 1 and 2), samples were sorted for biomass and ETS activity essay. At these stations, each Hydrobios net was subdivided: 50% for taxonomy (i.e. preserved in formol), 25% for population biomass estimates and 25% for ETS activity. For biomass estimate, the sub-sample (i.e. 25% of total sample) was fractionated with sieves in > 1000 □m and < 1000 □m size classes; these fractions were preserved at -20˚C. Sub-samples for zooplankton population ETS activity essays (i.e. 25% of total sample) were also sieved into the same two size fractions. As no Sanyo incubator was available for the ETS experiments, samples were incubated in a Pyrex plate filled with water and heated to 40˚C on a hot plate. Temperature of this 'hot tub' proved to remain constant during the required incubation time. ETS experiments were also performed on individual copepods, females and copepodite stage 5, of *Calanus glacialis*, *C. hyperboreus* and *Metridia longa*.

3) Respiration experiments

To derive respiration from the activity of the Electron transfer system a ratio of respiration on ETS activity is required. Thus incubations were carried out to measure oxygen consumption of copepods in sealed chambers. A Qubit® respirometry system was installed in the cold room at 0°C in the aft labs. The first experiment showed that the temperature in the cold room varied substantially and cyclically during the course of the measurement, decreasing the quality of the data collected. Another team experienced the same problem while measuring bacterial metabolism. For next leg, the Qubit® respirometry system will be installed in the cold room in the zooplankton lab on the front deck if it is possible to control its temperature. A new oxygen meter was stranded for weeks with the rest of the scientific equipment that did not make it with the crew change. This limited seriously our capability to carry out respiration measurements on zooplankton assemblages until we could get hold of our hand oxygen meter.

4) Taxonomic analysis of the zooplankton small size fraction

Every 2-4 days (depending on the net sampling possibilities), one 50µm tucker net sample was prepared for small fraction taxonomy. Most of the samples were analysed on the ship and the rest will be studied at Laval University. For each sample, 300 copepods specimens were identified under the stereomicroscope. A total of 9 samples were processed for small size fraction taxonomy during leg 6. For each sample preserved, one other 50 µm tucker net sample was preserved for biomass measurement. The codend content was filtered through a 1000µm sieve (in order to eliminate the

large organisms) then filtered through a 50µm sieve. The zooplankton was then placed on a preweighed GF/F filter that will be weighed back in Québec. Moreover, for every 50 µm sample analysed, the females *Calanus hyperboreus* and *Paraeuchaeta glacialis* were counted in one 200 µm Tucker net sample of the same cast. This counting will permit to estimate, related to the egg production rate experiments, the expected number of eggs in the 50 µm sample.

Acoustic monitoring

The Simrad EK-60 Echosounder of the Amundsen allowed our group to continuously monitor the spatial and vertical distribution of zooplankton and fish, the later mostly represented by Arctic cod (*Boreogadus saida*). The hull-mounted transducers are in operation 24h a day and will provide an extensive mapping of where the fishes are within the region of interest over a yearly cycle.

General Recommendations:

We will keep the same recommendations given on the leg-5 zooplankton team report:

As the drift of the ship while in a ice floe can be important, we recommend sampling every day with the Hydrobios and the 1-m^2 Square net in the moon pool and with the ring net from the ice. Sampling in the morning in the moon pool and from the ice in the afternoon prove to be the most convenient schedule for Leg-5 and 6

Low temperature is the essence of all the measurements done with live animals. The very warm temperature in our laboratory may pose problems even to the environment chamber which shows difficulties to maintain the required 0°C. The air conditioner system set at 22°C remedied to the problem. From now on, the AC should stay on and the laboratory door must remain closed.

When the ship is in transit, and that may last a few days, and then stops in a flow, particular attention should be given to the EK-60 sounder and the ADCP in order to make sure all sensors cleared of ice before the shutting down of the engines. Otherwise the data recorded are simply unusable.

More importantly, enjoy this amazing experience in this harsh but beautiful environment, have fun and KEEP THE SPIRIT!!!

THE ZOOPLANKTON SAMPLING TEAM

2.4. Team 5

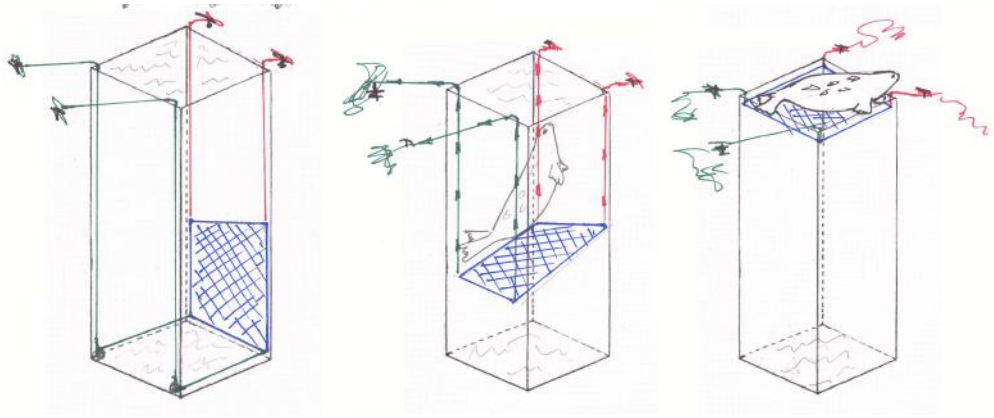
2.4.1. Ringed seal Tagging Project

PI: Steve Ferguson (DFO)
Project leader: Lois Harwood (DFO)
Project team: Tom Smith (EMC); Roger Memorana; Magaly Chambellant (DFO)

Background

Objectives
Understand movements and diving behaviour of seals from different age classes in the CFL area. Deploy satellite transmitters (PTT) coupled with time-depth recorders (TDR) on ringed seals using the CFL.

Methodology
Ringed seals have been reported to enter and use extensively the moon pool on multiple occasions during the CASES project. Seal capture will be performed from the moon pool on board the CCGS Amundsen. A net has been designed for this purpose and rely on the presence of ringed seals in the moon pool:



The net will be deployed in the moon pool in a "resting" position. When a seal enters the moon pool, the green ropes will be pulled up to close the moon pool and trap the seal. Both red and green ropes will then be pulled up to bring the seal to the surface. The seal will be captured, restrained, measured and a transmitter will be attached on its back before release.

Results

General information
Roger Memorana and Magaly Chambellant arrived on board the CCGS Amundsen on January 31st, 2008 for the beginning of leg 6a. Satellite transmitters and associated gear were brought back on board at the same time. Net parts were sent to Quebec in July and were stored in the cargo space on board the ship. Roger and Magaly were supposed to stay on board for 2 weeks, but decided to extent their stay by 1 week and live at mid-leg.

Logistic
Transmitters
Five SPLASH PTT/TDR from Wildlife Computers were programmed and tested successfully on February 1st, 2008.

Moon Pool
Attempts were made to obtain the exact dimensions and the different measurements of the moon pool from the original architect design. We succeed in obtaining some plans but no measurements were provided or were available at the time we left the ship. The moon pool is not perfectly squared and 2 pipes located on 1 side are preventing the net to perfectly fit the moon pool, created a gap of approximately 6"x88", big enough for a seal to escape. At mid-depth, a gusset and its extension is present in which the net can get caught. The pipes represents another trouble to pull the net up properly as the corners of the net can get caught in the pipes and create a gap between the moon pool and the net on the other side. Two "taquet" have been welded to the side of the moon pool on the rosette room side for people to lock the ropes quickly and easily in case of a capture.

Net
The aluminium poles to build the frame part of the net were not to be found anywhere on the ship. The mechanics team on board built us a metallic frame to replace the missing one and on February 6th, 2008, the net was ready to be deployed. After meeting with the Captain, chief officer and chief scientist, it was decided that the net should not be deployed, even in "resting" mode, when other activities would be taking place in the moon pool. The net will be deployed at night or during the day when the moon pool will be available. The moon pool will be left open every night, weather permitted, and an underwater light will be installed and left on. The best deploying position for the net in "resting" mode will be the have it lined up against the wall facing the pipes, just above the gusset and its extension. Ropes could then be pulled from the rosette room.

Ringed seals
An adult male ringed seal came in the moon pool during the night of 9-10 February, 2008. He was first spotted around 12:30 am and was observed up to around 3:00am; at what time, people when to bed. The seal was doing regular apnea of around 6 minutes and was resting on the surface for typically less than a minute. At around 7:00 am on the 10th, the seal was still using the moon pool and was staying at the surface for longer periods of time (around 5 minutes). It was last spotted around 9:00 this morning. At around 12:00pm, the same seal came back and used the moon pool with the same regular pattern as during the night but stayed longer and longer at the surface, eyes closed. At one stage, the seal started to splash heavily the water with its left fore flipper several times. He then stayed, apparently sleeping at the surface, for more than ½ hour. The seal eventually left around 13:45 when people from the ship came to weld pieces onto the moon pool side. The ringed seal came back twice very shortly around 20:10 but was very scared and disappeared as soon as it saw people. It came back around 23:45 and started to use the moon pool as before.

Capture
We deployed the net in the moon pool around 20:00 on February 10th, 2008. We attempted to capture the seal at around 12:30. While the seal was "sleeping" at the surface, we gently pulled the net to close the moon pool. Once trapped, the seal dove violently and bounced back when it hit the net. People pulling the "green" ropes had to keep pulling hard to prevent the seal to escape from the gap created between the net and the pipes in the moon pool. The net was thus deployed at an angle. The seal kept diving and bouncing back on the net until it found a small gap between the wall of the moon pool and the net and escaped. This gap was created due to the angle we gave to the net and the difference of pulling strength and lack of synchronisation from the 4 net deployers. We came to the conclusion that the net, as designed, was not functional to catch a seal, due to the configuration of the moon pool and the human factor.

After multiple trials and a lot of brain storming, a new net was designed using the mesh from the helicopter cargo (10" stretch mesh) and the same frame. Net deployment would be similar to the first net but the size of the mesh and of the net itself would make the difference. The new net is not tensed on the frame but instead is loose, creating a big pouch. The idea is that when the seal will be trapped and will dive, it will go down in the pouch, will not bounce back and eventually will get entangled in the mesh.

Trials of the new net in the moon pool were conclusive. Some drawbacks still persist though:

1) the mesh is not heavy enough to sink properly and there are risks for the seals to get entangled in the net when still in a resting position. This could result in the seal being drown without being noticed by the team.
   - a possible solution would be to attached a lead line or leads to the bottom of the pouch to have the mesh lying down the wall when the net is in "resting" mode

2) the net as built is relatively heavy and concerns have been raised on how heavy it will be to lift the net up when a seal will be caught.
   - an option would be to use a mesh made in monofilament like lumpfish nets used by hunters and scientists to catch ringed seals in the Belcher Islands.

3) it could be potentially dangerous and not very functional to pull up the net manually and with the rope provided.
   - an option would be to have a bigger rope and/or to use pulleys to pull up the net. There are good spots on top of the moon pool to fix such devices.

Conclusion

Even if no seal has been caught and deployed during the 3 weeks we spent on board, it was a very fruitful trip. We ruled out the net as designed in the first place as a good seal catching device in the moon pool and created a new design that should be more functional. We worked in close collaboration with the Captain, chief officer and crew members to deploy the net in the best conditions and improve our technique. It is too bad we were not able to try the new net out, but since we moved a lot after February 14th, no seal came in the moon pool. We are confident though that a future attempt to catch seal on board the CCGS Amundsen will have more chances to be successful.

Acknowledgements

We are thankful to all the crew members of the Amundsen and to our fellow scientists who helped in many ways to keep our hopes and motivation high, and to have made this trip a success after all. We would like to thanks particularly Martin for his endless dedication at watching the moon pool day and night; Pierre, Stephane, Nicolas and Pierre-Olivier without who we wouldn't have a functional net; Clement and Frederic who volunteered to be part of the seal catching team and get to pull many times on the ropes for nothing; and Stephane, Rene, Dan and Robbie who were very supportive of our work and made it possible.

2.5. Team 6

2.5.1. Gas Fluxes

PIs: Tim Papakyriakou (U of M), Helmuth Thomas (Dalhousie), Jean-Louis Tison (U.L.B.)
Participants: Frederic Brabant (U.L.B.), Bruce Johnson – 6a (U of M), Brent Else – 6b (U of M), Helmuth Thomas (Dalhousie)

Surface Meteorology and Flux Project
Brent Else

Introduction
The surface meteorology and flux program (CFL Team 6) is designed to record basic meteorological conditions and to study exchanges of momentum, heat and mass across the atmosphere-sea ice-ocean interface. The main value of this program to the overarching objectives of Team 6 is the direct measurement of CO_2 fluxes.

Fluxes of CO_2 are measured by the eddy covariance technique, which is dependent only on atmospheric measurements. Although measurement of these fluxes is extremely useful information, it is essentially meaningless without an understanding of the processes (physical, biological and chemical) that drive gas exchange. In an open-ocean situation this context is largely provided by measurement of sea-surface pCO_2, but the situation becomes much more complex when a sea ice cover is included in the equation.

This section of the CFL Team 6 cruise report reviews the atmospheric and sea surface pCO_2 measurements that were made during Leg 6. Other sections of the report will deal with the sea ice measurements that were made in support of the CO_2 flux measurements.

Micrometeorology and Eddy Covariance Flux Tower

Methods

The micrometeorological tower located on the front deck of the Amundsen (Figure 1.1) provided continuous monitoring of meteorological variables and eddy covariance parameters. The tower consists of slow response sensors that record bulk meteorological conditions (air temperature, humidity, wind speed/direction, surface temperature) and fast response sensors that record the eddy covariance parameters (CO_2/H_2O concentration, 3D wind velocity, 3D ship motion, air temperature) (Table 1.1). In addition, radiation sensors (Figure 1.1, Table 1.1) were installed on the roof of the wheelhouse to provide information on incoming longwave, shortwave and photosynethetically active radiation. All data was logged to Campbell Scientific dataloggers; a model CR5000 logger was used for the eddy covariance data, a CR1000 logger for the slow response met data, and a CR23X for the radiation data. All loggers were synchronized to UTC time using the ship's GPS system as a reference.

The eddy covariance system on the tower makes use of two separate gas analyzers and a single 3D sonic anemometer. The dual gas analyzers system allows us to make use of both closed path and open path eddy covariance systems. The open path gas analyzer has the benefit of making measurements concurrently with the sonic anemometer, but the closed path gas analyzer is not as easily disturbed by adverse weather conditions.

In order to make sure that the two systems are comparable, careful calibrations were performed on both instruments. The closed path system is based on a LI-7000 gas analyzer which employs two optical cells, one of which was used to monitor the drift of the instrument by constantly passing a stream of ultra-high purity N_2. In addition, the sample cell of the instrument was calibrated daily using the ultra-high purity N_2 to zero the CO_2 and H_2O measurements, and a reference gas of known CO_2 to span the instrument. Occasionally, a span calibration of the H_2O sensor was performed using a dew point generator (model LI-610). In the previous leg, we encountered a problem with the LI-7500 instrument under extremely cold conditions. In light of this problem, and given that atmospheric conditions make the LI-7500 very difficult to operate in the cold, the open path sensor was not used for the majority of this leg.

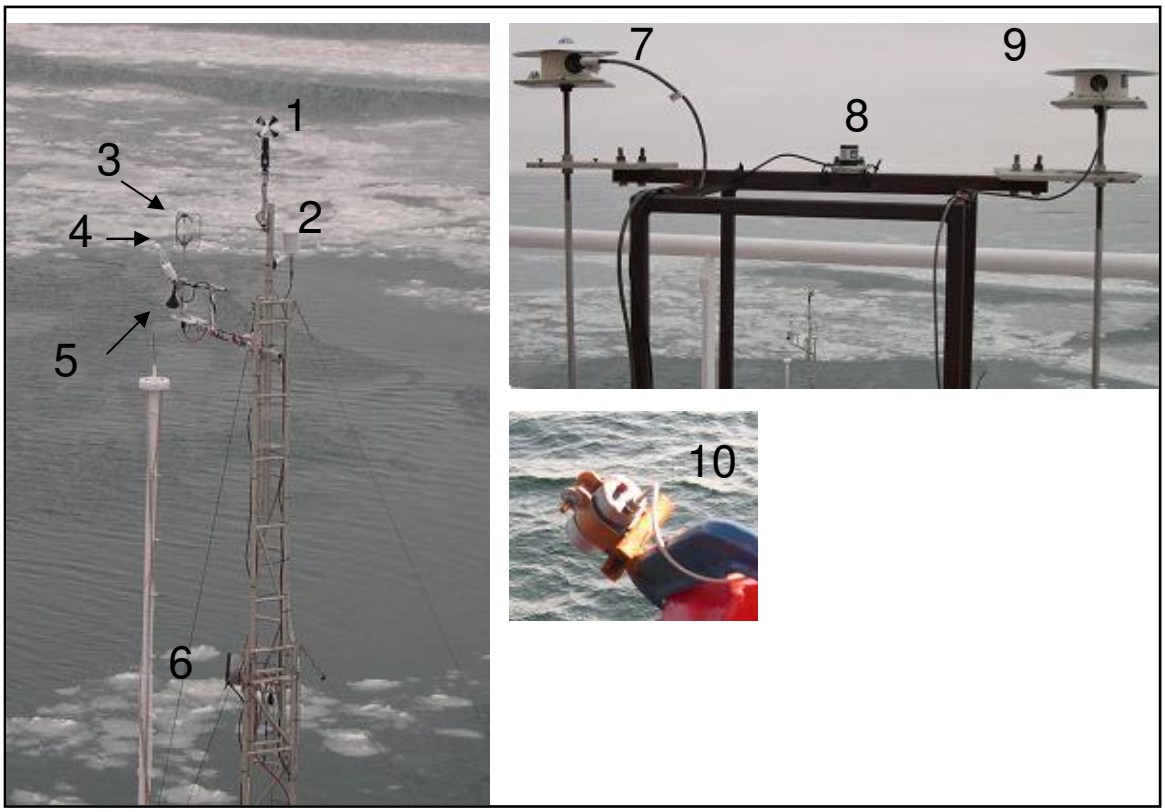


Figure 1.1: Meteorology and flux program instrument setup. See Table 1 for description of instruments based on the numbers. Note that on Nov. 18 the Motion Pak (6) was moved to the rear face of the tower to facilitate easier motion correction.

Table 1.1: Description of instruments shown in Fig. 1.1.

Sample data

As an example of the slow response meteorological data, Figure 1.2 shows the evolution of air temperature and wind speed over one day at Station D29 (a first year sea ice floe with a mean level ice thickness of ~120cm). An example of the rapid response flux data is shown in Figure 1.3, which shows 10 minutes of vertical wind speed and CO_2 concentration. A great deal of processing will be required to calculate actual fluxes of CO_2, and to filter out erroneous data.

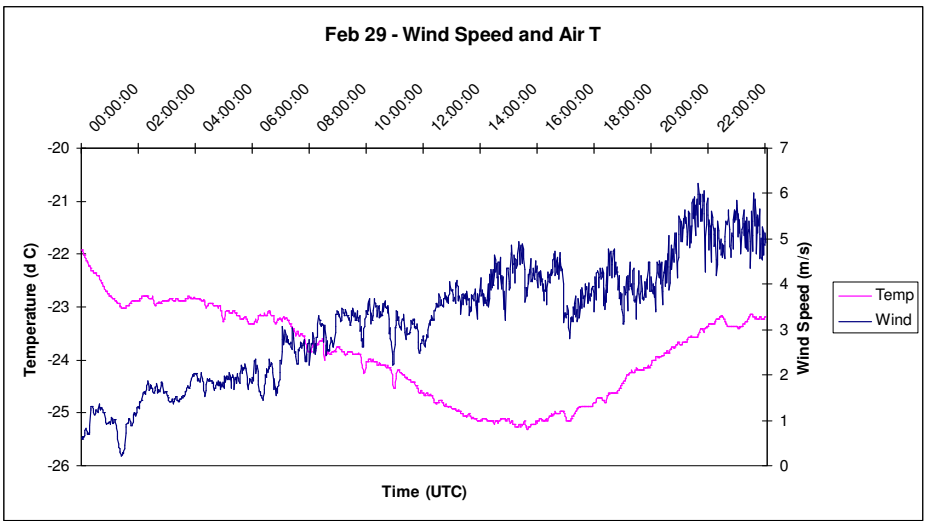

Figure 1.2: Slow response meteorological data example; wind speed and air temperature (24 hrs).

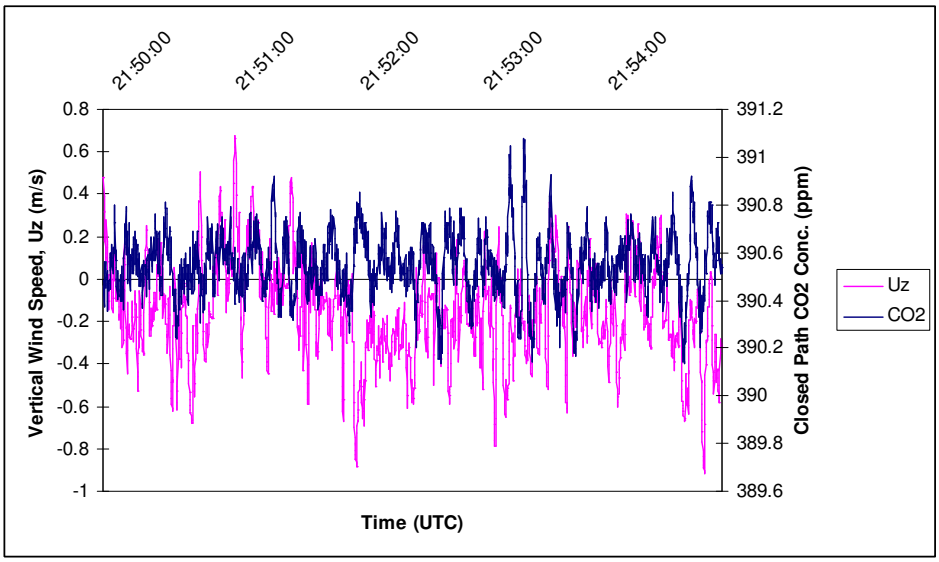

Figure 1.3: Fast response flux data example; vertical wind speed and closed path $_{CO2}$ concentration (10 min).

Notes
The meteorological tower ran consistently for the duration of the leg (Jan 30 –Mar 13) with the exception of brief periods when the tower was taken down for maintenance. However, for significant periods of time during the leg certain sensors were inoperable due to atmospheric conditions. The most common problem encountered during this leg was riming due to the cold, moist conditions. The extent of data lost due to atmospheric conditions cannot be estimated at this time, and will only be known once post processing is complete.

On-track pCO_2 System
Methods
A custom-built pCO_2 system was utilized on this leg to measure dissolved $_{CO2}$ at the sea surface in near real time. The system (Figure 1.4) is located in the engine room of the Amundsen, and draws sample water from the ship's clean water intake. The water is passed into a sealed container through a shower head, maintaining a constant headspace. This set up allows the air in the headspace to come into equilibrium with the CO_2 concentration of the seawater, and the air is then cycled from the container into a LI-7000 gas analyzer in a closed loop. Thermocouples are used to measure water temperature immediately before entering the equilibration chamber, and to measure the temperature of the air in the chamber. All data is logged to a Campbell Scientific CR1000 datalogger.

The LI-7000 gas analyzer was calibrated daily using ultra-high purity N_2 as a zero gas, and a gas with known CO_2 concentration as a span gas. Spanning of the H_2O sensor was not necessary because a desiccant column removes H_2O from the air stream before passing into the sample cell. As with the closed path system, a stream of N_2 is constantly cycled through the reference cell of the LI-7000 to monitor and correct for drift of the instrument.

Figure 1.4: The on-track pCO_2 system located in the engine room of the Amundsen. The equilibration chamber is the clear cylinder (left bottom) and the gas analyzer is the box with the digital display.

Sample Data
Figure 1.5 shows an example of a single day of CO_2 data recorded by the on-track system, along with water temperature. Further processing must still be undertaken to correct the values for changes in temperature that occur due to the length of the sample line, and to properly calculate pCO_2.

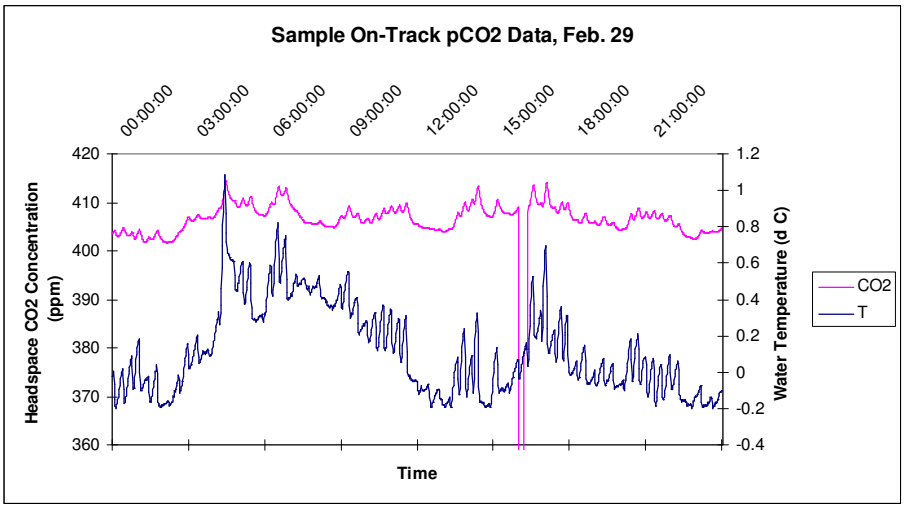

Figure 1.5: Sample on-track pCO_2 data (CO_2 and water temperature). The drop in pCO2 at 15:00 corresponds to a calibration run.

Notes
The on-track pCO_2 system was active for the duration of the leg, with some minor interruptions for maintenance. Major interruptions in data collection were experienced when the ship was breaking ice, which either reduced the flow of water into the equilibration tank, or completely blocked it. In the case of blocked flow, the data is lost, but tests will have to be conducted to determine if data obtained with low water flow is useful. The only change to the system on this leg was the addition of an electric solenoid valve that is triggered by a floating switch if the water level becomes too high.

CO2 in Sea Ice Project
Brent Else/Frederic Brabant

Introduction
The primary focus of Team 6 is to gain a better understanding of the cycling of climatologically important gases in Arctic seas. A large base of knowledge already exists regarding air-sea gas exchange, but considerably less is known about the exchange of gases in an ice covered ocean. During CFL Leg 6, a sampling program was carried out to examine CO_2 in sea ice with the goal of creating a context against which measurements made by the eddy covariance flux system (section 1) can be interpreted.

To gather this contextual information, several different methods were used to understand the distribution of CO_2 in sea ice. To determine fluxes of CO2 directly associated with the sea ice, a flux chamber was used. This sampling provides a very unique dataset that will allow us to understand the state of sea ice with respect to CO2 early in the ice growth season. Ice cores and surface water samples were also taken to analyze DIC/TA content.

Peepers
No peepers were deployed during this leg, in an attempt to conserve some peepers for the upcoming fast ice camp.

Brine Sampling
No brine samples were attempted during leg 6a due to personnel constraints. During leg 6b, attempts to collect brine were made, but the cold temperatures made it difficult to obtain a measurable amount of brine.

Flux Chamber

Methods

When measuring fluxes of CO_2 with the eddy covariance system, there is always some ambiguity regarding the "footprint" of the measurement. This is a problem when dealing with a highly spatially variable icescape such as the one encountered in Leg 6. To resolve some of this ambiguity, a flux chamber was deployed over certain ice types to directly measure the flux of CO_2.

The flux chamber is a sealed cylinder connected the LI-820 gas analyzer used in the peeper and brine experiments (Figure 2.1). Gas is continually cycled through the chamber and the analyzer in a closed loop, and 1 second measurements are recorded as 30 second averages on the CR10X datalogger. A small fan in the top of the flux chamber homogenizes the air to ensure that a gradient of CO_2 does not build up in the chamber. The theory of operation is quite simple – if the concentration of CO_2 in the chamber changes, a flux of CO_2 must be occurring related to the sea ice. Normally, ice cores were taken in conjunction with these measurements for salinity and temperature profiles.

Figure 2.1: Deployment of the flux chamber. Gas analyzer is located in the white cooler.

Sample Dates and Locations

During Leg 6, we were able to collect flux data over very thin ice; something we have not measured in previous legs. The thin ice that was sampled was either "artificially created" by the broken track behind the Amundsen, or in natural leads.

Table 2.1: Deployment dates and locations of flux chamber. All times UTC.

Station	Date/Time	Notes
D26	Feb 26, 2245	-3 runs on 17cm ice behind ship
D26	Feb 27, 2230	-3 runs on 22.5 cm ice behind ship
D26	Feb. 28, 2145	-3 runs on 23.5 cm ice behind ship
D26	Feb. 28, 2330	-3 runs on new natural flaw lead near the ship (5cm thk)
D26	Feb. 29, 2230	-3 runs on 26.5 cm ice behind ship
??	Mar. 1, 2100	-2 runs on 16cm ice at newly formed lead
??	Mar 4, 1700	-2 runs on 15cm ice at newly formed lead

Sample Data

Figure 2.2 shows sample data from a run over thin ice at a newly formed lead near station D29. The data shows a clear outgassing of CO_2. This is an interesting result that was not observed in previous legs.

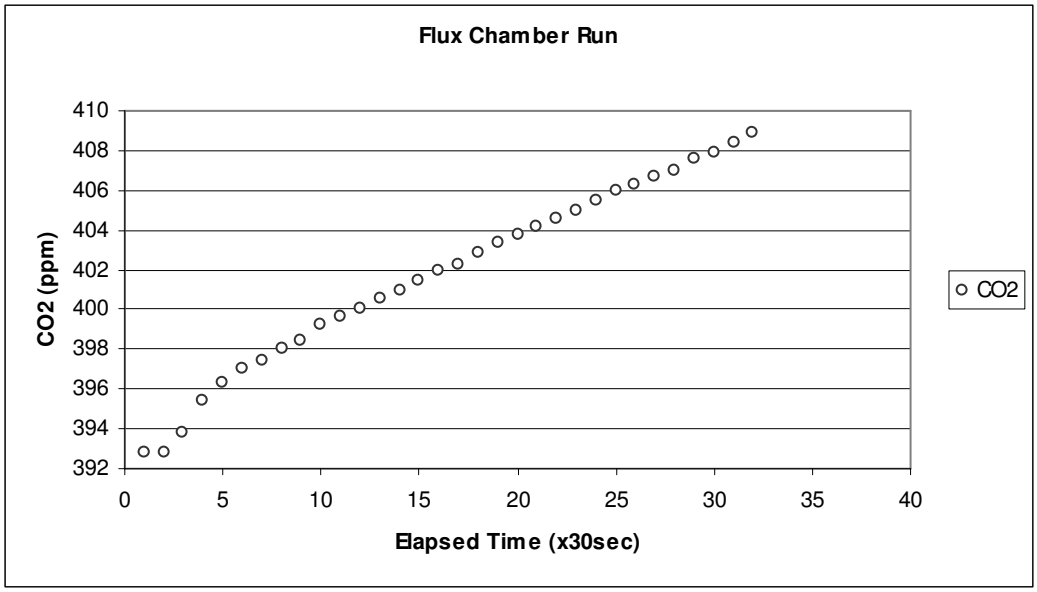

Figure 2.2: Sample flux chamber data over newly formed lead, Feb 28 (5cm thick)

Dimethyl Sulphur (DMS) Project
Frederic Brabant

Introduction
I was here as a PhD student from Universite Libre de Bruxelles (U.L.B.) to go on with the collaboration between Belgian (team leaders: Dr Jean-Louis Tison and Dr Bruno Dellile) and Canadian scientists on CFL studying the sea ice biogeochemistry in a climate change perspective within Team 6 (Gas Fluxes). As previously mentioned, this collaboration is expected to continue until the end of Leg 8B.

Aim of the study
In order to better understand the impact of the sea ice biogeochemistry on the dynamic of the climatically significant gases (CO_2, DMS), multi-parametric analyses have to be conducted. The table below (Table 3.1.) shows the measurements that are routinely performed in the framework of such a multi-parametric analysis.

Table 3.1: List of parameters that will be analysed by the Belgian members of Team 6

List of Variables
Temperature
Salinity
$\delta^{18}O$
Thin Sections
DMS,P,O
Total gas content
O2, N2, CH4, Ar, CO2
Nutrients
Chla
Iron and TM

As previously mentioned, such a data collection should allow a better understanding of the processes driving the gas dynamics in sea ice at different periods of the year, necessary for further modelling purposes. In the framework of both Gauthier Carnat's project (University of Manitoba – Legs 4B, 8 A&B) and my own research project, I was focusing during this Leg on the dynamics of CO_2

(collaborating with Brent Else and Bruce Johnson on this leg) and DMS (and related compounds DMSP and DMSO) both within the sea ice cover and at its interfaces (atmosphere and ocean).

Material and methods

Field measurements

The participation to CFL Leg 6 A&B, allowed us to sample and perform measurements on cold winter sea ice (main station with complete set of biogeochemical variables), which is of primary importance since few studies have been previously focused on this period of the year. As already mentioned above, the opportunity was also given, during this leg, to sample and carry out fluxes measurement on newly formed ice ('flux chamber' stations with CO_2 flux measurement at the ice surface, ice temperature and salinity at 2 cm resolution). Location and sampling time of the main stations are given in the table below. See above for the information above the 'flux chamber stations'.

Table 3.2 Location and sampling time of the main stations

Date	Coordinates	Type of station	Average ice thickness
02/06/2008	N 71°04.623 W 124°49.009	Complete	59 cm
02/25/2008	N 70°58.250 W 123°54.970	Complete	123 cm
03/08/2008	N 71°01.357 W 123°51.765	Complete	124 cm

For each station the work has been organized as follows:

1) Ice sampling: a minimum of 10 ice cores has been taken for each main station, using our non-contaminating drilling equipment. Each core is generally dedicated to the study of one variable of the variables given in the table 3.1. A short description of each core (breaks) was made on the field. Most of the ice cores will be shipped back to Winnipeg or Belgium for further analysis. Ice cores have also been taken for people from other teams.
2) In-situ data collection: using a temperature probe and a drill, the ice temperature has been measured at 5 cm resolution. The same resolution will be used for the other parameters. Once back on the ship, this temperature core is processed for bulk salinity measurement. Other general observations have also been made on the field including temperature, freeboard and snow thickness measurements. The next figure shows an example of those observations for one station.

Laboratory work

Here below is a list of the variables measured on the ship or of the samples prepared for further measurement.

Salinity and $\delta^{18}O$

Using a calibrated conductivimeter, bulk ice salinity has been measured on melted ice samples at a resolution of 5cm for the main stations and 2m for the 'flux chamber stations'. The same water was then used to fill in small $\delta^{18}O$ vials for further analysis.

Chl_a

With the help of Dr. Maria Estrada (ICM, Barcelona), the Chl_a level was measured for each main station. Considering the low Chl_a levels usually observed in the ice during this time of year (very low light input), we decided to filter melted ice for every 15 cm instead of the usual 5 cm spatial resolution. This represents a total amount of 20 measurements.

DMS, DMSP, DMSO

Using a special 'dry- extraction technique by crushing', Dr. Maurice Levasseur's "purge and trap system" and a gas chromatographer, we analysed the DMS concentration in the ice at a spatial resolution of 5 cm for the main stations for a total of 63 measurements. See Gauthier Carnat's report (leg 4B) for further details about the method.

By addition of NaOH pellets to the crushed ice, we turned DMSP into DMS and measured 63 concentrations of DMSP. Ice powder from each sample was collected in 20 ml vials for further DMSO measurements in Belgium.

In total, more than 120 samples of ice, water and brines were analyzed.

Other Variables

Additional studies (see table 3.1) will be undertaken in Brussels or Winnipeg later this year, when the ice cores will have been shipped back from the Arctic.

Example of data

As an example, we show some results and profiles obtained during the cruise.

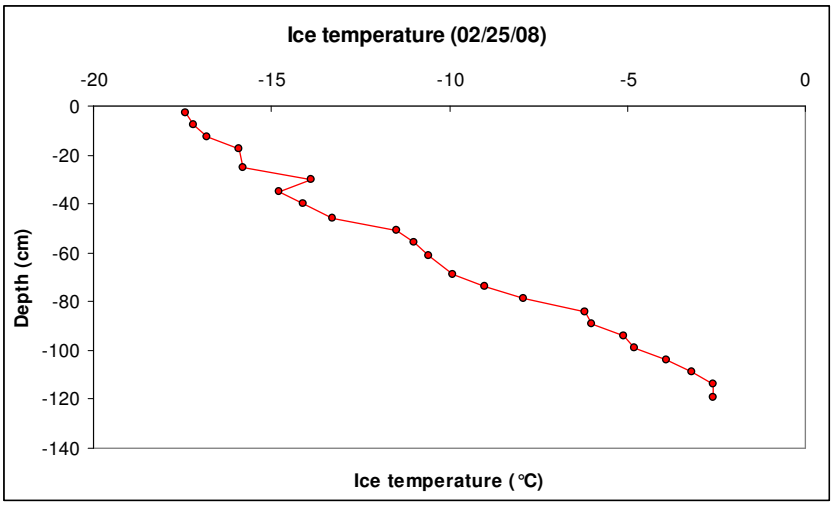

Fig. 3.1 Temperature profile for station 02/25/08

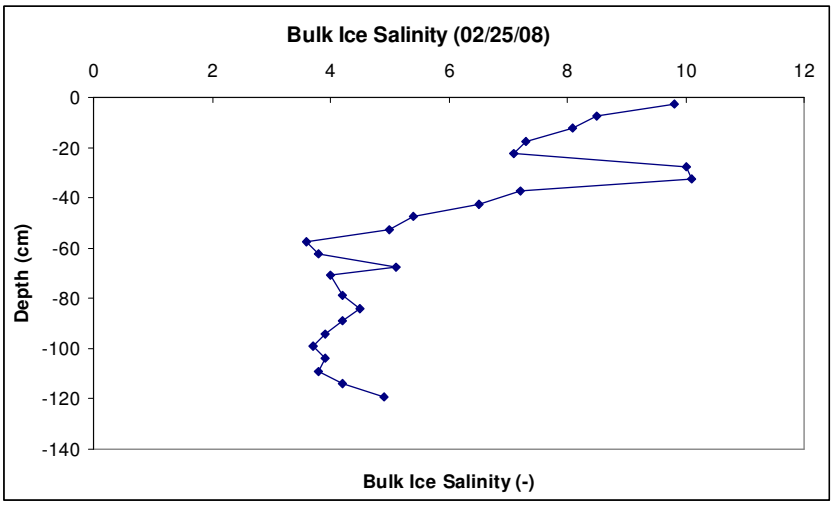

Fig. 3.2 Salinity profile for station 02/25/08

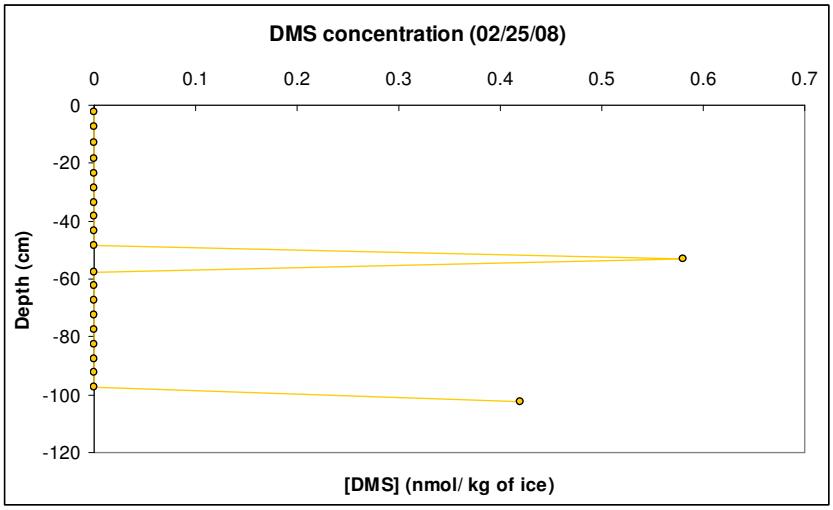

Fig. 3.3 DMS profile for station 02/25/08

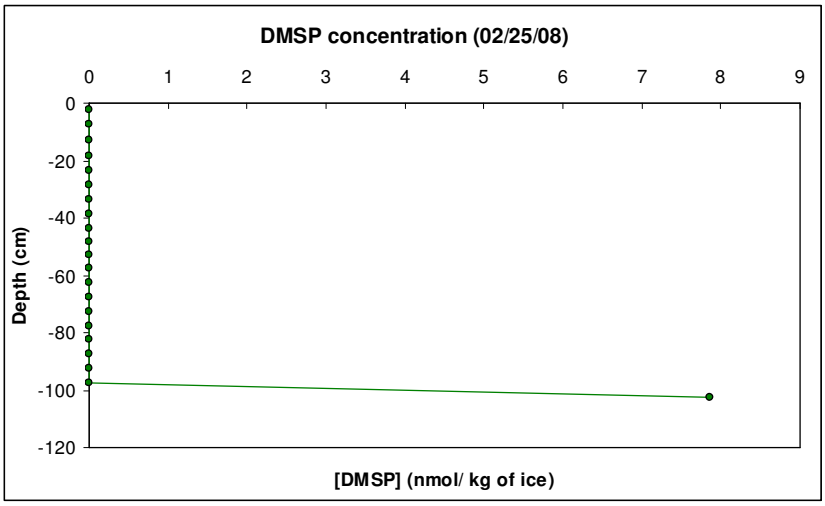

Fig. 3.4 DMS profile for station 02/25/08

Outreach

We took part in some outreach activities during this leg what giving us the opportunity to let people from general public know a bit more about the importance and the interest of the CFL experiment. We worked in collaboration with Bartley Kives and Wayne Glowacki (Winnipeg Free Press) in order to publish a popularization article as well as an interactive slideshow mainly focused on Team 6 research activities during CFL. Oportunity was also given to accompany students from the 'Schools on Board' program during fieldtrip and laboratory activities.

Dissolved Inorganic Carbon (DIC)/Alkalinity Project

Brent Else

Introduction

During this leg, DIC/TA samples were occasionally taken from ice cores and from surface water under the ice. The purpose of this study was to support flux measurements (chamber and tower) by observing the carbon dynamics within the ice and immediately below it. This also augments DIC/TA samples taken from the CTD/Rosette, since surface water cannot be sampled through the moon pool. Due to personnel constraints, no samples were taken during Leg 6a, and samples were limited during Leg 6b. However, samples of thin ice were taken in Leg 6b, which helps fill a data gap from previous legs.

Methods
Where ice was thick enough, conventional ice cores were taken. The cores were packaged in a well-sealed core sleeve, and transported in a box with cold packs frozen at -80 ^{0}C to the cold lab (-20 ^{0}C) on the ship. In the cold lab the cores were immediately sectioned and placed into gas impermeable Tedlar bags. The bags have a small valve, from which air was removed using a vacuum pump. The core samples were allowed to melt at room temperature, and were then transferred into DIC bottles, spiked with $HgCl_2$ and analyzed for DIC/TA. Over thin ice, samples were extracted by more crude methods (saws, ice chippers) and placed directly in the Tedlar bags. From that point, the same procedure as above was conducted.

For surface water samples, several methods were used for sample collection. When sampling on the ice (conventional cores) a small pump was used to collect surface water. When sampling over thin ice (i.e. in the ice cage) water was either sampled by carefully immersing the DIC bottles, or from a Niskin bottle. Whenever possible, pH samples were taken as well. Generally, surface casts using a portable CTD were made in conjunction with surface DIC/TA/pH samples.

Sample Dates/Times/Locations
Table 4.1 lists the samples taken during Leg 6.

Table 4.1: DIC/TA/pH sample locations/dates

Station	Date/Time	Notes
??	Mar 1/2200	-Sampled bulk ice, surface water and 1m water for DIC/TA in newly formed lead (ice thickness 16cm)
D29	Mar 8	-DIC/TA core, with surface water sampled by pump. pH for surface water.
D30	Mar 9/~2230	-DIC/TA at 1m, 5m, 15m and 30m from Niskin bottle in ice cage over open lead. 2 hours later sampled newly formed ice for DIC/TA (2cm thick).

2.5.2. OASIS

Team members: Jan Bottenheim[1], Ralf Staebler[1], Alexandra Steffen[1], Patrick Lee[1], Paul Shepson[2], Phil Tackett[2], Jim Whiteway[3], Jeff Seabrook[3], Vlad Popovici[3], Udo Friess[4], Leif Vogel[4], Denis Poehler[4]

[4] Universität Heidelberg

Introduction
In 1986, independent reports of surface O_3 depletion were published from the Arctic coastal Global Atmospheric Watch (GAW) stations Alert and Barrow (Bottenheim et al., 1986; Oltmans et al., 1986). This depletion appeared to occur after Polar sunrise hence suggesting that this was a photochemically driven process. Pursuit of a causal relationship in photochemical O_3 destruction led to the discovery by Barrie et al. (1988) that O_3 depletion occurred in concert with large increases in particle-phase bromine, leading the authors to hypothesize the following chain reaction:

$$Br + O_3 \rightarrow BrO + O_2 \qquad (1)$$
$$BrO + BrO \rightarrow 2Br + O_2 \qquad (2)$$

This hypothesis is now confirmed through the observation of tropospheric BrO radicals during O_3 depletion episodes (Hausmann and Platt, 1994). Observations from space show enhanced BrO columns in polar spring over areas exceeding 10 million square kilometers in sea-ice covered Polar Regions (Richter et al., 1998) but to date only limited, short term observations have been made on the ocean surface, mostly near Alert, NU (Hopper et al., 1994, 1998; Bottenheim et al, 2002; Morin et al., 2005). A major gap in understanding the depletion chemistry is the role of various oceanic surfaces in halogen activation and subsequent O_3 and Hg depletion (Simpson et al., 2005).

Since the discovery in 1995 of atmospheric mercury depletion events (MDEs) at Alert, NU, (Schroeder et al., 1998) the understanding of cycling of Hg in the polar atmosphere has dramatically changed. During the spring elemental Hg is transformed in the atmosphere to a more reactive species that appears to be deposited to snow and ice. Models suggest that up to 300 tonnes of Hg could be deposited to the Arctic environment each year from MDEs alone (Lu et al., 2001), but cause and effect are still uncertain. For instance, the location where MDEs originate is unclear, key processes involved in creating the depletion episodes are poorly identified, and the identity of the atmospheric end-products is still largely a mystery. As a result it is also unclear whether the bulk of the deposited Hg enters the ecosystem or is reemitted into the atmosphere once the snow melt starts.

The various OASIS activities on board the Amundsen under the umbrella of IPY-CFL aim to improve our understanding of the details of these ozone and mercury depletion episodes. Direct measurement of halogen oxides and halogenated VOCs by Phil Tackett & Paul Shepson (Purdue) will shed light on the ozone destruction chemistry. Measurement of BrO using one active DOAS and two passive MAX-DOAS instruments by Leif Vogel and Denis Poehler (Heidelberg) will give us information on the spatial and temporal variations of BrO. Vertical ozone profiles are obtained using an ozone LIDAR operated by Jeff Seabrook, Vlad Popovici and Jim Whiteway (York). A sodar provides wind profiles and information on the structure of the boundary layer, which will be related to the ozone profiles (Ralf Staebler, Environment Canada). An ozone eddy covariance flux system has been added to the energy & CO_2 flux system at the bow of the Amundsen (Ralf Staebler). And last but not least, a mobile measuring system constructed by the Environment Canada OASIS team, the so-called OOTI (Out-On-The-Ice) sled, is being deployed on surfaces thought to be active sites of heterogeneous chemistry to determine their relative significance, to measure ozone, mercury and energy fluxes as well as BrO and the micrometeorological conditions.

Atmospheric Halogen Chemistry

Philip Tackett, Purdue University

As part of the OASIS campaign, I investigated Arctic surface-to-atmosphere interactions through the quantitative measurement of halogen oxides and various halogenated volatile organic compounds (VOCs). With support from the National Science Foundation's Office of Polar Programs (USA), a new chemical method was developed at Purdue University for the quantitative determination of halogen oxides during 2007. This new method was first deployed aboard the CCGS *Amundsen* as part of the Circumpolar Flaw Lead System Study during IPY 2007-2008. This method operates by drawing halogen atoms and halogen oxides into a flowing chemical reaction chamber, where they undergo rapid reaction with a fluorinated alkene and nitric oxide to produce a stable ketone product that is detected by gas chromatography with electron capture detection.

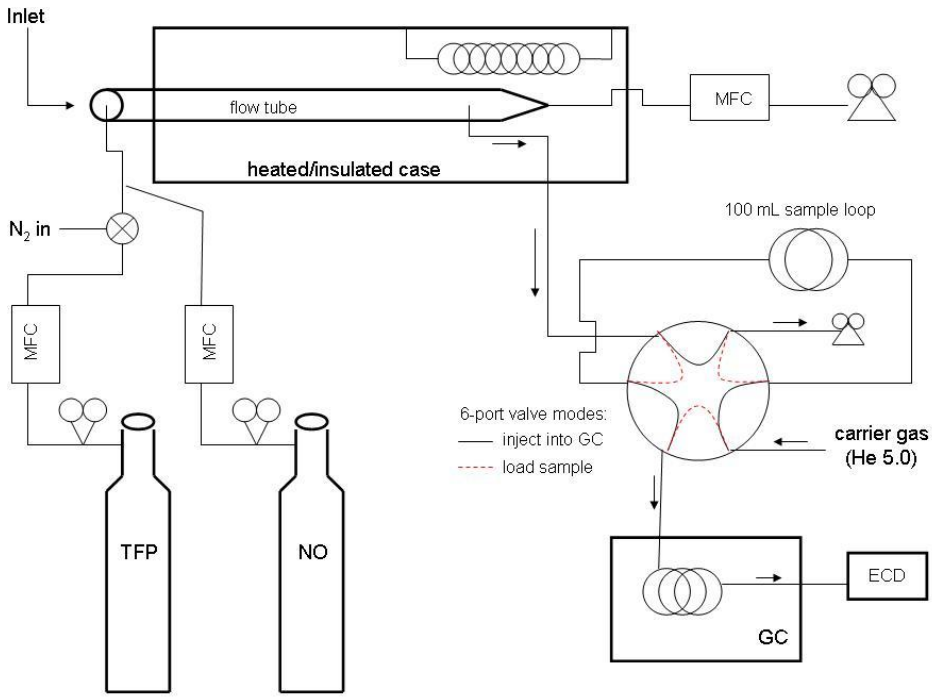

Fig 1**:** Complete flowing reaction chamber instrument schematic

The instrumentation arrived on the *Amundsen* on 2 Feb 2008, and was operational on 5 Feb 2008. Samples were collected throughout Leg 6, during various weather events and sampling locations. As expected, halogen oxides (specifically BrO) remained undetected until the local ozone concentration decreased from the typical ambient mixing ratio of approximately 40 ppb. Several halogenated VOCs, including bromoform and dibromomethane, were detected at varying mixing ratios throughout the duration of the campaign, even when halogen oxides were not detected. There were two very brief nighttime periods of ozone depletion upon which halogen oxides were detected, which is likely due to the advection of ozone-depleted and halogen-enriched air from beyond the local atmosphere. These were followed by a 48-hour period of continuous ozone depletion in early March, in which ozone dropped to a mixing ratio of less than 10 ppb. Halogen oxides were also detected during this time period, and dropped below the limit of detection upon the eventual rise of ozone concentration.

Fig 2**:** Reaction chamber mounted above instrumentation container

The instrument was deployed in a container on the uppermost deck of the vessel, with the reaction chamber mounted above the container. Special care had to be taken to ensure that the samples being collected were not affected by exhaust from the ship's stacks, located just aft of the container. The crew aboard the *Amundsen* during Leg 6 was of invaluable assistance throughout the campaign, helping to provide a well-equipped laboratory in a location ideal for the investigation of surface-to-atmosphere interactions. The data collected from this instrumentation will be combined with data from other CFL participants, including ozone, wind, and potential temperature vertical profiles, atmospheric mercury, and meteorological data, to develop a better understanding of the Arctic atmosphere and its interactions with the significantly changing sea ice conditions.

DOAS Measurements

Leif Vogel, Heidelberg University

As part of the OASIS project, the Institute of Environmental Physics (IUP), University Heidelberg, Germany is participating in the Circumpolar Flaw Lead by conducting remote sensing measurements of atmospheric trace gases in the planetary boundary layer. The applied Differential Optical Absorption Spectroscopy technique (DOAS) determines concentrations of gases of interest via their absorption structures in the measured spectral region. The main goal during Leg 6 and the first half of Leg 7 is the observation of Bromine Explosion, the sudden increase of BrO concentrations in the PBL with subsequent Ozon Depletion Events. Also other gases absorbing in the measured spectral range can be evaluated.

The measurement instruments are one passive Max-DOAS instrument and one Long Path DOAS (LP-DOAS) instrument. The Max-DOAS consists of an temperature controlled OceanOptics USB2000 spectrograph connected to an external telescope head via an optical fibre in order to measures spectra of scattered sunlight in a wavelength range between 310nm and 385nm at different elevation angles. Compared with sunlight at zenith angle, trace gases along the light paths of the respective elevation angle can be determined in the lower troposphere. The LP-DOAS instrument on the other hand uses an artificial broadband light source to send a collimated beam of light to retro-reflectors placed on the ice at 1.5km to 5km distance of the ship. The reflected light is measured at the ship with an Acton 300 spectrograph and contains absorption structures of the gases to be studied. Comparison of light which is send with the backscattered one allows the deduction of trace gas concentrations along the light path.

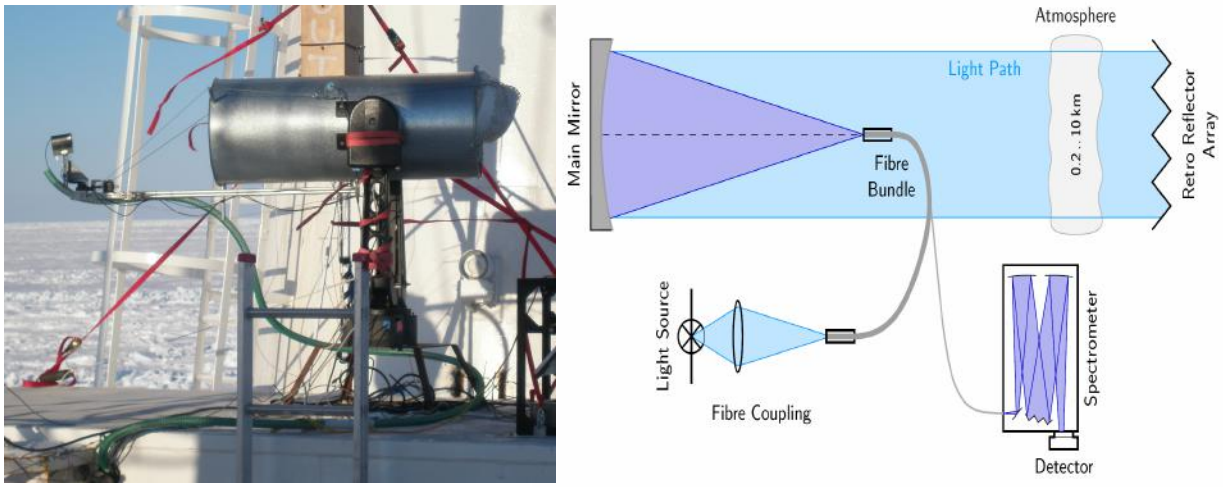

Fig. 3: (Left) LongPath DOAS set up. (Right) Telescope mounted on top of the OASIS container

Setting up the LP-DOAS was completed during the first week of leg 6. The loss of more than half of the available retro-reflectors during a snowstorm with subsequent movement of the ship was a major

setback. Unfortunately further tries of retrieval were unsuccessful due to the rapid movement and change of the ice caused by the strong winds.

Further measurement time was limited by the weather conditions and the necessity of ship movements, along with restrictions on possible light paths lengths.

The Max-DOAS instrument was installed on the 15th of Februar and is collecting data since. First data evaluations yield BrO concentrations below the detection limit until the end of February. Since the February 29th, BrO could be detected in low quantities on several days, but further data analysis and correlation with other measurements are necessary.

Ozone LIDAR Measurements

Jeff Seabrook, York University

The OASIS Tropospheric Ozone LIDAR is designed to measure back-scattered laser light in 4 separate wavelengths. By knowing the absorption characteristics of these wavelengths in regards to ozone, as well as their atmospheric scattering properties an ozone profile can be determined by directly comparing the backscatter signal of any 2 of these wavelengths. The LIDAR was installed at the beginning of LEG 6 and operated successfully for the first half of this leg.

Due to a malfunction of a critical component of the LIDAR transmitter (the laser head) that needed repair by the manufacturer, the LIDAR was non operational from Feb 20th to March 4th. The laser head was removed from the LIDAR and taken to the manufacturer in Bozeman, Montana, for repair on Feb 25th; these repairs were completed on Feb 29th.

On March 3rd we were able to return onboard with the repaired laser head and integrate it back into the LIDAR.

Since becoming operational on March 4th the LIDAR has performed well and has yielded some potentially interesting preliminary results regarding ozone concentrations during an ODE.

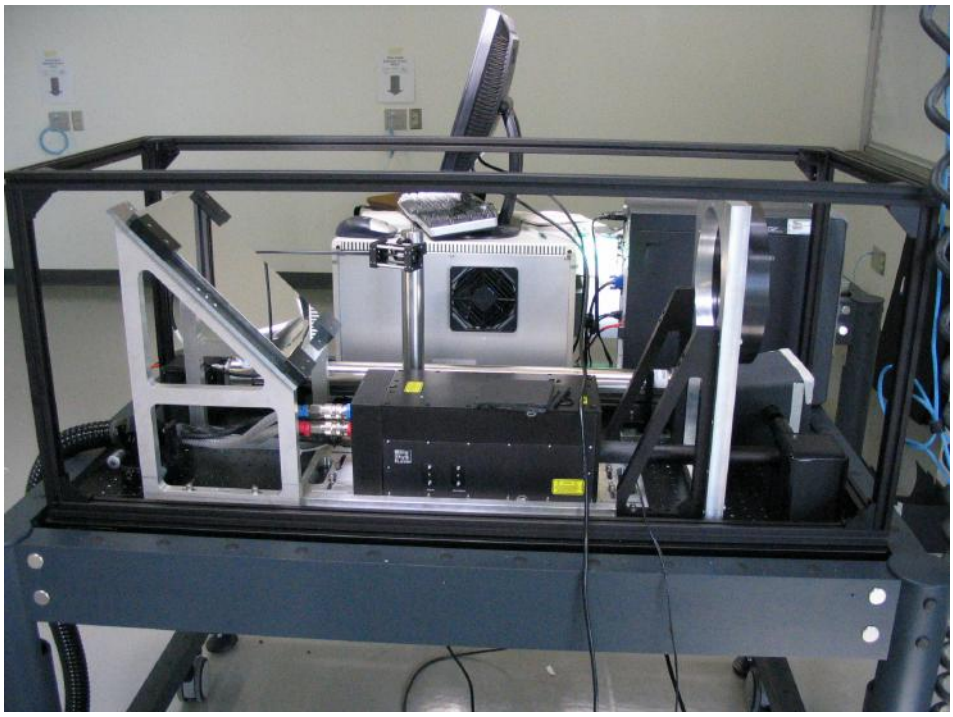

Fig. 4 Tropospheric Ozone LIDAR

OOTI Sled, Sodar and O_3 Fluxes

Ralf Staebler, Environment Canada

The OOTI (Out On The Ice) sled is a mobile measurement platform that has been developed at Environment Canada over the last 4 years, and earlier versions have been deployed at Alert as well as Barrow. The instrumentation consists of a MAX-DOAS (see 3. for details), vertical gradient systems for ozone, gaseous mercury and carbon dioxide, coupled with a sonic anemometer, a temperature profile, and basic meteorological parameters.

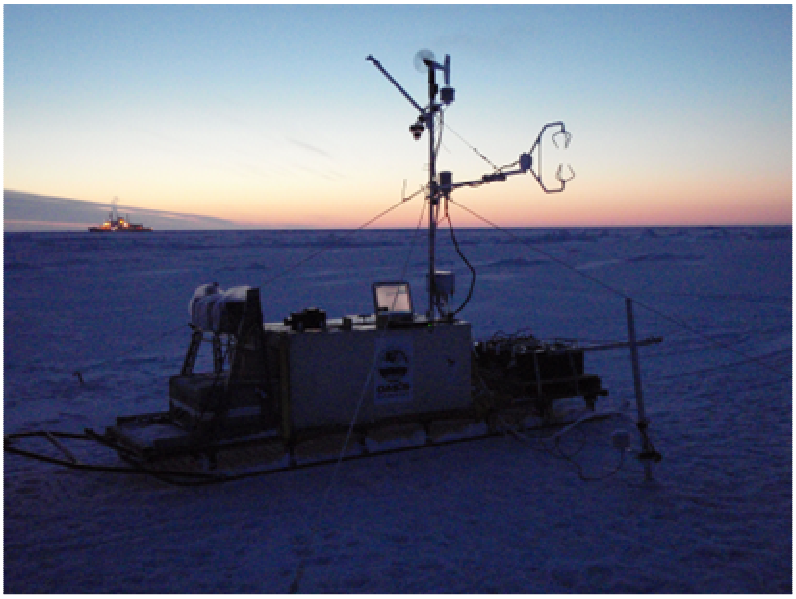

Fig. 5. The OOTI sled, about 1.2km east of the Amundsen, on 8 March 2008

This year, the OOTI Sled came off to a rough start. The computer responsible for data acquisition and instrument control inside the OOTI box was damaged beyond repair in transit from Toronto to the Amundsen, and a replacement had to be set up from scratch. It took more than 10 days to complete this job and involved a lot of improvisation, but on 5 March 08 the sled was deployed with (almost) everything working. The first site was 1.2 km west of the ship on ice about 1m thick. Late on 7 March 08 the sled was moved to relatively young ice (30cm thick) about 1 km east of the ship. We plan to deploy the sled as much as feasible over the next 3 weeks, and results will be shown in the report for Leg 7a.

The sodar (a Scintec MFAS with nominal range of 1000m) was set up for the first time on 6 March 08 about 50m east of the ship. Optimization of the operating parameters is still in progress. This instrument will let us relate the vertical profile of O3 with the thickness the stable boundary layer that develops in calm conditions and discern the relative importance of dynamics (i.e. mixing into the boundary layer from the free troposphere) and chemistry.

Fig. 6. The Scintec MFAS sodar next to the ship on 9 March 2008

The "fast ozone analyzer", an instrument based on detecting ozone by monitoring the photons produced in the chemiluminescent reaction of ozone with nitric oxide, has been operational since 2 March 08. It is set up to sample air in parallel with the CO_2 instrumentation in the Hg/CO_2 flux container on the bow of the ship, at a frequency of 10Hz, in order to calculate eddy covariance fluxes between the atmosphere and the surface. This will let us quantify the importance of surface uptake of O_3 in its overall budget in the lower atmosphere.

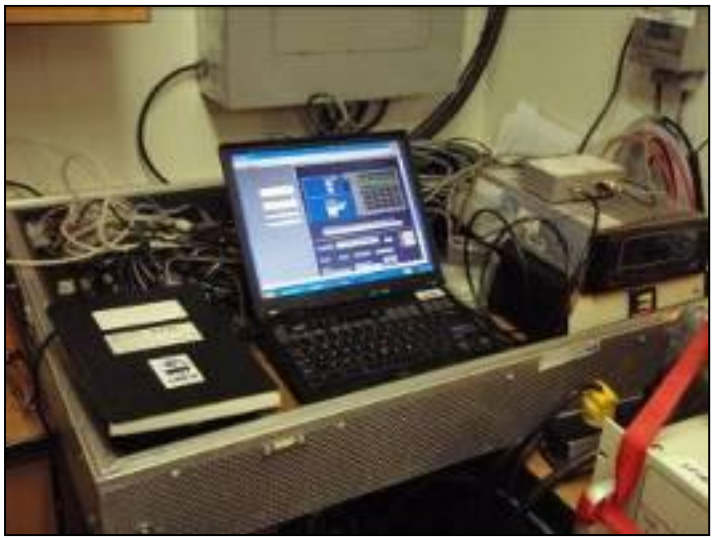

Fig. 7. The O_3 Eddy Covariance Flux Instrument

2.5.3. Dissolved Inorganic Carbon System (CFL Teams 6 & 7)

PI: Helmuth Thomas
helmuth.thomas@dal.ca, Department of Oceanography, Dalhousie University, Halifax, NS, Canada
Participants: Helmuth Thomas, Amanda Chaulk (Univ. Manitoba, Winninpeg), Frederic Brabant (Univ. Brussels, Belgium), Brent Else (Univ. Manitoba, Winninpeg)

submitted by Helmuth Thomas
05.03.2008

The ocean's exchange of carbon dioxide with the atmosphere is governed by the biogeochemical cycling of carbon and physical processes throughout the water column, which determine the concentration of dissolved inorganic carbon (DIC) and total alkalinity (TA) in the surface waters. Out of the four measurable carbon system parameters (DIC, TA, pH and pCO_2), a minimum of two are needed to calculate the others and fully describe the inorganic carbon chemistry, over-determination of the system being beneficial. During CFL Leg 6, a total of 140 samples were analyzed for dissolved inorganic carbon and total alkalinity and to a lesser extend for pH, yielding two, and for some stations, three relevant parameters.

Water samples were collected in parallel with the weekly, or once per station nutrients rosette. Individual 250 ml bottles were used for DIC and TA, and pH was collected in a smaller plastic bottle. DIC samples were first to be taken from the Niskin bottles, and pH and TA followed immediately at individual casts and depths. If possible, DIC and TA samples were analyzed within 24 hours of sampling. The remaining samples were spiked with $HgCl_2$ and were stored in the dark at 4°C.

DIC and TA were analyzed on board using a VINDTA 3C (Versatile Instrument for the Determination of Titration Alkalinity) by Marianda. TA was determined by titrating a volumetrically accurate subsample using 0.1n HCl as titrant. For DIC analysis, a volumetrically determined subsample was acidified with 8.5% H3PO4 to convert all inorganic carbon into gaseous CO_2. The CO_2 is then stripped out of the sample using ultra-pure N2 gas, transferred into a coulometric titration cell and detected using the coulometric method (Johnson et al., 1993). Samples were analyzed for pH using a HP 8453 spectrophotometer; pH was be calculated using the absorbances measurements obtained from the coloration of water samples with Phenol Red and Cresol Purple.

In addition to water column sampling, an attempt was made to continue (to a lesser extent) the ice core work initiated by team 6 on the previous legs. To this end, ice samples were collected at drift stations. The top, middle, and bottom 10 cm of the core were cut and placed in plastic Tedlar bags – gas impermeable, with a clamp type seal and small spigot for withdrawing air or water. The ice samples were laid out to thaw then transferred to DIC bottles. These samples were analyzed for DIC, TA, and conductivity. In parallel, surface water samples were taken with a hand-held niskin bottles from below the ice and the upper meters of the water column

Table 1: Stations sampled for DIC, TA and pH during leg 6 (until March 6)

2.5.4. Barium (CFL Teams 6 & 7)

PI: Helmuth Thomas
helmuth.thomas@dal.ca, Department of Oceanography, Dalhousie University, Halifax, NS, Canada

submitted by Helmuth Thomas
05.03.2008

In the Canadian Arctic, barium (Ba) is mainly released from the North American continent and can therefore be used as a tracer for terrestrial freshwater input. Together with ^{18}O, a tracer for freshwater input from precipitation and ice melt, all freshwater sources to the Arctic can be quantified, thus providing complementary information to the CO2 system studies.

Samples for barium were taken from the rosette parallel to samples for ^{18}O, at approximate depths 5, 10, 25, 50, 75, 100, 150, 200 and 500 m. 15 ml nalgene bottles were rinsed three times, then filled and

spiked with 15 µl concentrated HCl. Sample bottles were sealed with parafilm and taken for later analysis using isotope dilution mass spectrometry.

2.6. Team 7

2.6.1. Carbon & nutrients fluxes

PI: Jean-Éric Tremblay (Laval University)
Samples taken by Clément Clerc and Marie-Emmanuelle Rail

Samples for nutrients and urea have been taken at the following stations:

Station	Date	Latitude	Longitude
2007-19D	04/02/08	71°04.627	124°48.998
2007-19D	08/02/08	71°04.614	124°48.942
2008-19D	11/02/08	71°04.547	124°48.127
2008-22D	18/02/08	71°19.333	124°31.870
2008-26D	25/02/08	70°55.960	123°56.158
2008-26D	29/02/08	70°50.736	123°36.779
2008-27D	02/03/08	70°45.607	123°27.461
2008-29D	08/03/08	71°00.940	123°46.478
2008-29D	11/03/08	71°00.940	123°46.478

Water was sampled at the following depths:
salinity of 33.1, 10, 20, 30, 40, 50, 60, 80, 100, 120, 140, 160, 180, 200, 250, 300 and every 100 m up to the bottom.

Nutrients and urea samples are all frozen and will be analyzed on a further leg.

2.6.2. Marine Microbiology Group

Participants: Marta Estrada, Laura Alonso (Carles Pedrós-Alió team: Institut de Ciències del Mar, Barcelona, Catalonia, Spain), Beatriz Fernández (Connie Lovejoy team: Québec Ocean et Department de Biologie, Université Laval, Québec city, Québec, Canada

Introduction
Microorganisms are a heterogeneous group that include representatives of the three kingdoms of live, Archaea, Bacteria and Eukarya. Because of this heterogeneity these organisms accomplish key biogeochemical processes in the ecosystem. Autotrophic microorganisms are the base of the Arctic ocean trophic web, which comprises 7 orders of size magnitude, from the smallest cell, less than 1 µm microorganisms, to the largest mammals on the order of meters. All these organisms are strongly influenced by the lack of light during part of the year, the low temperatures and the ice cover. Comparing the species composition and activities of microbial communities in systems with diverse

chemical and physical regimes is a good way to learn more about the importance of the different forces that determine how microbes use organic and inorganic matter and how this influences other components of the food web. This knowledge is needed to better predict the consequences of natural or anthropogenic changes on these trophic dynamics. This will also help us to evaluate the system's ability to buffer these changes at short and long timescales.

Objectives
Our group had an ambitious sampling program to be completed during this leg. The different protocols done though this leg covered the work of 4 teams: Corina Brussard, Connie Lovejoy, Roxanne Maranger and Carles Pedrós-Alió. These protocols addressed different aspects of the microbial world, with the objective of giving a detailed view of the microbial diversity and processes occurring during the winter season.

Sampling
The sampling for this leg took place at the south and southwest off the coast of Banks Island. The comparison of samples gathered during the different wintering legs will allow a better understanding of the seasonal dynamic and the comparison of the different geographical areas will provide valuable information on the diversity and depth distributions of microbes.

Since the beginning of leg 6, we sampled at 5 stations (D19, D22, D26, D27, D28). The sampling dates and the localization of the stations can be found on Annex 1. Our strategy was to obtain microbiological data from specific water masses through the water column with a special focus on the nutricline, the upper mixed layer, and the deep waters. These water masses were identified during the downcast of the CTD, based on the readouts from the temperature, salinity, oxygen, nitrate, fluorescence, transmissometer and pH probes.

When possible, surface water from about 2 metres detph was collected through holes in the ice. These samples will be compared to the 12 meters surface water collected from the moon pool inside the ship.

Variables Sampled
A table summarizing the samples obtained during leg 6 can be found on Annex 2. A brief description of the protocols follows.

1. Molecular genetics

a. DNA sampling. Samples for DNA were collected on every station at 4 different depths. During DNA collection water was prefiltered through a 50 µm mesh, excluding larger organisms to be collected. Water was then filtered through a 3 µm polycarbonate filter and the same water was again filtered through a 0.2 m filter. This sampling protocol gives two different samples, one containing the DNA from 50 µm to 3 µm fraction (Large fraction) and one containing the 3 µm to 0.2 µm fraction (Small fraction). After collection samples are keeped at -80 ºC until processing in the Lovejoy laboratory in Université Laval. These samples will give valuable information on the biodiversity and distribution of microorganisms.

b. Metagenomic library

On station 2008-D26 (cast 78) we took 14 litters at 60 metres (temperature inversion) that were filtered for RNA. This specific sample will be used to construct a metagenomic library once the sample is processed in the laboratory off the ship.

2. Gene expression

Samples for RNA were collected on every station at 4 different depths. During RNA collection water was prefiltered through a 50 µm mesh, excluding larger organisms to be collected. Water was then

filtered through a 3 µm polycarbonate filter and the same water was again filtered through a 0.2 m filter. This sampling protocol gives two different samples, one containing the RNA from 50 µm to 3 µm fraction (Large fraction) and one containing the 3 µm to 0.2 µm fraction (Small fraction). After collection samples are keeped at -80 ºC until processing in the Lovejoy laboratory in Université Laval. These samples will give valuable information on the spatial expression of key genes.

3. Chlorophyll concentration

Samples for chlorophyll analysis were taken on each station at six or seven different depths. For each sample, one liter of water was filtered through a Whatman GF/F filter. This was the so-called large fraction, comprising all microorganisms larger than the nominal pore aize of 0.7 In addition, water was prefiltered through a 3 µm pore filter to obtain the small fraction, which was finally filtered through a Whatman GF/F filter. Afer filtration, the filters were stored overnight at -20ºC. Subsequently, the filters were introduced in acetone 90% and placed in a refrigerator, in the dark. After 24 hours, the fluorescence of the extracts, before and after acidification with 3 drops of 5% HCl, was determined by means of a Turner TD-700 fluorometer. As can be seen in Annex 4, the chlorophyll concentration in the CFL stations has been decreasing steadily since last fall.

4. HPLC

Samples for High Performance Liquid Chromatography (HPLC) analysis were taken on each station at six different depths. Two fractions were collected, one for the total fraction (down to 0.7 µm) and one for the small fraction (from 3 µm to 0.7 µm). Samples were stored at -80 ºC and will be analyzed at Laval University.

5. Virus

Different variables associated with viruses have been collected.

a. Viral abundance

Flow cytometry samples for six depths were collected at every station.

b. Burst Size

Transmission electronic microscopy samples were collected for six depths at two stations.

c. Viral production

Virus free seawater was added to a bacterial concentrate and incubated with mytomicine C during 12 hours. Samples without mytomicine C are compared with the mytomcine C samples in order to obtain an estimate of virus production on infected cells (lytic and lysogenic cycles). Viral production was followed taking samples for flow cytometry each 3 hours.

d. Viral diversity

2 litters of surface seawater were concentrated on 50 mL using a Vivaflow system (30 kd cartridge). This concentrate will be used to analyze the diversity of viruses present in the surface seawater.

6. Silicon – isotopes

Three different depths were sampled in order to obtain information on Si isotopes. Seawater was filtered through a 0.6 µm polycarbonate filter. The filters and the filtrate were stored to be processed on land.

7. Organic matter

Using pre-combusted GF/F filters (47 mm diameter) in a passive filtration system (by gravity) samples for dissolved organic carbon (DOC), total organic carbon (TOC), amino acids and carbohydrates were taken. Samples without filtration for total phosphorus determination were also collected.

8. Bacteria and Archaea abundance

Microscope preparations for bacterial abundance estimations were prepared by filtering a small volume of water (20ml) fixed with formaldehyde and staining with DAPI (which bounds to the DNA). Microscopy slides were prepared on all stations at 6 different depths. Slides were frozen (-20°C) until counting on a microscope.

Bacterial preparations were also obtained in some stations using glutaraldehyde instead of formaldehyde as the fixative. These slides were frozen at -20 ºC and counted onboard using the Olympus BX51 epifluorescense microscope onboard.

9. Eukaryotic microbes abundance

Microscope slides for eukaryotic abundance estimations were prepared filtering 100 mL of seawater fixed with glutaraldehyde and staining with DAPI (which bounds to the DNA). Microscopy slides were prepared on all stations at 6 different depths. These slides were frozen at -20 ºC and counted onboard using the Olympus BX51 epifluorescense microscope onboard.

10. Ciliates

Samples for ciliates abundance and diversity were collected and preserved using a Lugol acid solution. These samples will be analyzed off the ship.

11. FISH: eukaryotes

The Fluorescent In Situ Hybridization is a powerful technique to study specific groups of microorganisms. Samples for FISH were collected on all stations at 6 different depths. Samples were stored at -80 ºC until analysis off the ship.

12. CARD – FISH: bacteria and archaea

Samples for the abundance and distribution of specific groups of prokaryotic microbes were collected in all stations at 6 different depths. These samples have been frozen at -20 ºC until its analysis with different oligonucleotide probes off the ship.

13. MarFISH: bacteria and archaea

Incubations with 3H-labeled leucine and C14-labeled bicarbonate were carried out to detect active prokaryotes in the uptake of these substrates at all sampled stations at a minimum of two depths (surface and base of the nitrocline). Leucine incubations lasted for 8 hours and bicarbonate incubations lasted for 24h always in the dark. After fixation of the samples, they were filtered and the filters were stored at –80 to be analyzed off the ship. In combination with the FISH technique this can give information on the phylogenetic identity of these active microorganisms.
Beside the MarFISH incubations, samples were incubated with C14-labeled bicarbonate (at a lower concentration) to measure bulk bicarbonate uptake by bacteria and archaea in the dark. These samples were incubated for 24 hours and subsequently filtered. The filters were exposed to HCl fumes overnight, and embedded in cocktail for the scintillation counter measurement.

14. Bacterivory – FLBs grazing

In order to acquire values of ingestion rates of bacteria by heterotrophic eukaryotes, Fluorescent Labelled Bacteria (FLB) obtained from a culture of *Brevundimonas diminuta* were used on bacterial grazing experiments. Three replicates and a 0.2 µm seawater filtered control with 10^5 cells/ml added were used. Samples for flagellates and bacterial microscopy observation and for bacterial production were collected at the beginning and after 48 hours of incubation at seawater temperature (cold-room).

15. Alguivory – Micromonas grazing

Two grazing experiments with the *Micromonas* strain RCC497 were performed in order to calculate an ingestion rate of *Micromonas* cells by heterotrophic flagellates. For each experiment, two replicates of 2000 ml seawater filtered by 200 µm were incubated during 96 hours, at surface seawater temperature (-1.4 ºC). A control of 0.2 µm filtered seawater was run in the same conditions at the same time. Samples for FISH (to observe *Micromonas* ingestion) and flow cytometry (to observe *Micromonas* disappearance) were taken.

Incubations were run at the second half of the leg, as the *Micromonas* cultures brought from Barcelona had to adapt to the incubation conditions onboard. Once the exponential growth of the cultures was achieved, experiments were run.

16. Bacterial production

Bacterial production rates were measured using the leucine incorporation method (^{3}H labelled leucine) with 4 hours of incubation in coolers filled with ice-cold seawater in the radioactive lab. Samples were taken at every station at six depths, and also from surface waters below the ice. Rates of incorporation of radio labelled leucine were measured using the scintillation counter onboard.

17. Respiration

Bacterial/community respiration rates were measured using the FIBOX, which measures O_2 depletion in time using sensors glued to the bottom of 500ml Erlenmeyers. The consumption of O2 in time can be converted in CO2 production to compare carbon respiration rate to bacterial carbon production rates. Each experiment lasted for about 15 days and oxygen measurements were made every 1-2 days. The Erlenmeyer were kept in the dark inside a cooler in a cold room. An ongoing experiment from the previous leg was followed and a new experiment was started at station 26D.

18. ETS

Due to the low respiration rates in Arctic waters, a back-up method was also employed to obtain respiration rate surrogates via ETS (Electron transport system activity). This is achieved by filtering a large quantity (8L-10L) of water on GF/F filters to collect live cells and freeze them (-80°C) as quick as possible. Once off the ship, filters will be defrozen and the living cells will be subject to various enzymatic tests to measure activity.

19. N_2O

Dissolved N2O measurements were carried out using the headspace equilibration method with 1.1 L of seawater. 3 samples were taken from 3 depths and will be analyzed off the ship for N2O on an electron capture detector (GC).

Experimental program

1. BrdU incubations

Incubations with the timidine analogue bromodeoxiuridine (BrdU) were carried out during 4 weeks. On a periodic basis DNA samples were taken. Once off the ship these samples can be used to determine the identity of the active microbes on the incubations using antibodies specific for the BrdU incorporated to the DNA of the microorganisms.

2. Archaea enrichment

Laura Alonso followed with the archaeal experiments set up by Pierre Galand on leg 4. The objective of those experiments was to enrich bacteria or archaea that have a chemoautotrophic lifestyle in the Arctic, and study their rates of dark bicarbonate uptake. For that reason incubations were started at leg 4 in order to promote labile organic carbon consumption by heterotrophic bacteria through time. Two incubations were amended with ammonia and phosphate while the other two did not present any nutrient addition. At the beginning of leg 6 (about 3 months later) samples were taken from the incubations to measure dark bicarbonate uptake (using C14-bicarbonate) and we found higher rates than those found in in situ samples, what suggested the growth of chemoautotrophic organisms in the cultures after organic carbon depletion. Then, about 15 L of each incubation were filtered by 0,2 microns in order to have labil organic carbon depleted waters free of bacteria. This water was used to start new incubations (regrowth experiments) with the inoculum of fresh bacteria from in situ samples, or bacteria from the cultures set up on leg 4. Replicate seawater cultures with and without the addition of ammonium were followed every 3-4 days (Annex 3). Samples were taken for DAPI preparations, FISH, and flow cytometry. FISH and flow cytometry samples will be processed off the ship. Microscopic anaylisis of DAPI preparations was done on board in order to follow the growth of bacteria in the cultures. Towards the end of the incubations samples were taken for bicarbonate uptake, bacterial production, MarFISH with leucine and bicarbonate and DNA analysis.

3. SIP experiments

Incubations amended with C13-labeled bicarbonate were carried out during 4 weeks in the dark at the cold room. DNA samples were taken every week from replicate bottles. Once off the ship these samples will be used to try to isolate the DNA of those organisms taking up bicarbonate in the dark.

4. Microcosm experiments

Some phytoplankton culture experiments carried out during CASES 2003-3004 indicated that there could be substantial chlorophyll *a* concentration increases with little or no apparent consumption of nitrate-N, suggesting that, at a short time scale, dissolved organic nitrogen (DON) could be a major source of N for phytoplankton growth (either directly or trough remineralization). During leg 6 of CFL, a microcosm experiment was designed to test whether polar phytoplankton would utilize urea as a nitrogen source, as some studies carried out two decades ago had suggested. Water collected from 12 m depth at station 19D was distributed in eighteeen containers, which were subjected (in triplicate) to treatments combining high (30 µmol photons m^{-2} s^{-1}) or low (0.5 µmol photons m^{-2} s^{-1}) light with no nutrient amendments, addition of nitrate or addition of urea. After two weeks of incubation, and at the end of the experiment, samples were taken for determination of chlorophyll, phytoplankton, nutrient and organic carbon concentrations. MarFISH incubations with 14C urea were also carried out with subsamples from the microcosms and with surface water of several stations. An evaluation of the results of this experiment will have to wait until the measurements to be carried out on land are available.

Other activities

The whole team participated in all social activities of the ship and in the schools on board program. Laura gave a talk ("Microscopic life in the Arctic") and Marta and Bea did some lab activities with

the students. Marta also wrote a dispatch to be published on the CFL webpage. Laura and Beatriz were responsible for the maintenance of the MilliQ system. We three also helped the zooplankton team on the digging of holes in the ice and sampling. We also provided 0.2 µm filtered seawater for them. Finally Beatriz continued a Spanish course that was started by Laura Sims during the first 3 weeks.

Acknowledgements
The cruise was a success and we are grateful to our Chief Scientists (Rob McDonald and Gary Stern), Captain Stephan Julien and crew of the Amundsen for the excellent work done during leg 6. We would like to thank Clement Clerc and Marie Emmanuelle Rail for CTD Rosette operations, Steeve Gagné for technical assistance and the zooplankton team, Anaïs Aubert, Helêne Cloutier, Gerald Darnis and Louis Letourneau, for assistance in under ice surface water sampling.

2.7. Team 8

PI: Gary Stern (DFO, Freshwater Institute)
Participants: Joanne DeLaronde (DFO, Freshwater Institute), Alexis Burt (MSc student, University of Manitoba), Amanda Chaulk (MSc student, University of Manitoba), Jeff Latonas (MSc student, University of Manitoba), Patrick Lee (Environment Canada)

General objective
This question this project hopes to answer is how climate variability in physical forcing and the biogeochemical response to this primary forcing will affect hexachlorocyclohexane (HCH) and mercury (Hg)/methyl mercury (MeHg) contaminant cycling. Ultimately, we propose to relate changes in delivery and biogeochemical cycling of these contaminants to their levels in fish, marine mammals and the people who consume these tissues as part of their traditional diets.

2.7.1. Organic contaminants

Hexachlorocyclohexane (HCH) (DeLaronde)

Technical HCH is a mixture of several isomers, the most abundant being α-HCH (60-70%), β-HCH (5-12%) and γ-HCH (10-15%). Technical HCH and pure □-HCH (lindane, pesticide active isomer) have been used for over 50 years and are now ubiquitous in water throughout the northern hemisphere with the highest levels found in the surface water layers near pack ice in the Arctic Ocean.

Technical HCH was banned or heavily restricted by China, the former Soviet Union and India between the mid-1980s and 1990. Concentrations of α-HCH in arctic air responded quickly to these large-scale usage changes and declined by an order of magnitude from the early 1980s to mid-1990s in steps that closely matched global usage and emission estimates. As a consequence, the direction of net gas exchange in arctic waters reversed from deposition in the 1980s to air-water equilibrium or volatilization in the mid-1990s.

The α-isomer is the prominent in Arctic air, water, biota and soil, and moves northward via cold-condensation, a process whereby the contaminant evades into the atmosphere, drifts with atmospheric currents, and condenses in colder climates where at colder temperatures increasingly favours the water and extensive ice cover inhibit further evasion. Hence the contaminant accumulates disproportionately in the Arctic.

Water sampling
Water (4L) was collected from the rosette from 10m, 25m, 50m, 100m, 150m, 200m, 300m and the bottom where possible. Through a hole in the ice away from the ship, water from the water/ice interface and 5m was collected using a Niskin bottle. In the lab, water was pumped through a glass-fiber filter followed by an ENV+ solid-phase extraction (SPE) cartridge using peristaltic pumps. Filters and cartridges are frozen and brought back the Freshwater Institute for analysis. $^{18}\delta O$ were also collected at each site and depth where HCH samples were taken.

Twenty eight HCH water samples were collected during leg 6 from the following stations; D19, D23 and D26.

Air Sampling
The air sampler was set up on the bow of the ship on the starboard side along with each ice sampling. Samples are collected on a glass fiber filter and polyurethane foam (PUF) for analysis of organic contaminants. Air samples collection time ranged between 4 and 10 hours. Filters and PUFs were frozen at -20°C and shipped frozen back to the FWI for HCH contaminant analysis.

Air samples were collected at stations D22, D23 and D26.

Ice sampling
Ice samples for HCHs concentration and enantiomeric composition were collected. The samples for oxygen isotope composition ($\delta^{18}O$) and salinity were taken along with all ice samples. The ice samples were collected in collaboration with team 2 and the ice microstructure and physical analysis was made on all of them (see team 2 cruise report). Ice cores were cut according to ice microstructure into 8-30cm layers, melted (4-8L of water) and pumped through a glass-fiber filter followed by an ENV+ solid-phase extraction (SPE) cartridge using peristaltic pumps. Surface water (4L) was sampled along with every ice sampling using a Niskin bottle. The cartridges and GFFs were stored in -80 °C and brought to the DFO (Winnipeg) for analysis.

Ice cores were sampled for HCHs from stations D22, D23 and D26.

2.7.2. Mercury

Ice sampling
Snow, frost flowers and ice samples were taken to follow the movement of mercury and its forms through the snow/ice interface and the ice/brine interface. Both new (nilas) and old ice were sampled. All ice was characterized with microstructure, temperature and salinity measurements. All coring activities coincided with Team 2. At Station D19 where a mercury depletion event was observed, surface snow was collected in triplicate 3 to 4 times daily to generate a time series of mercury deposition and revolatilization. New Ice was sampled when the opportunity presented itself. Sampling was facilitated both from the ship being lowered in the cage, and being harnessed at the ice edge of an open lead. Team 8's ice sampling efforts were also featured on the front page of the Winnipeg Free Press ☺.

Ice Collection: D27, D29

Water (Hg)
During leg 6 the Portable In-Situ Laboratory for Mercury Speciation (P.I.L.M.S.) became operational after many challenges. Broken glassware, contaminated tubing, and interference from helicopter flights and ship transit were some of the challenges that had to be overcome. Both the total mercury analysis system and dissolved gaseous mercury analysis system are operational and samples are being run as much as possible. Preparations are underway to begin operation of the methyl mercury analysis system during leg 7.

Water was collected from the moonpool via rosette for Hg profiles (15 depths) along with corresponding ^{18}O and salinity samples. To complete the Hg profile, water from the water/ice interface and from 5 m was collected out on the ice either at the zooplankton sampling hole or at an auger hole. These depths cannot be accurately sampled through the moonpool due to contamination from the moonpool itself. We have found that water collected by the moonpool rosette down to a depth of 12 m is contaminated for mercury sampling purposes. At least 50 ml of water is collected in duplicate from each depth into Falcon Tubes. The samples are returned to PILMS and analyzed as soon as possible (preferably within one day) by CVAAS (cold vapor atomic absorption spectroscopy).

Water depth profiles from the rosette were sampled at stations D19, D22, D27 and D29(x2).

Water from the water/ice interface and from 5 m was sampled at; D26, D28(x2), D29(x4). The sampling at these stations coincided with mercury depletion events.

Algae Cores (Hg)
Cores were collected for bottom ice algae with a trace metal clean core barrel.
The bottom ice will be stored frozen and freeze dried to collect the algae. The algae will be processed for THg, MeHg, stable isotopes and fatty acids at the Freshwater Institute (DFO Winnipeg).
Ice coring for algae Hg analyses

Ice coring for Hg analyses in under ice algae.

Atmospheric Mercury Measurements
Among the parameters being measured are Gaseous Elemental Mercury (GEM), Particulate Mercury (Hg_p), Reactive Gaseous Mercury (RGM), and Total Mercury (Hg_t). GEM measurements began in Leg 5, RGM and Hg_p measurements began on February 8th 2008, and Hg_t measurements began on February 11th. These parameters have been measured continuously from their respective start dates with some down time due to routine maintenance on the instruments, ship movements, and adjustments made to the configuration.

Figure 6: Tekran 1130/1135 speciation unit with 1105 pyrolysis unit

There were some issues installing an intake manifold originally designed for the system due to problems with the original measurements and sample dilution from zero air generated by the 1130 system. The intake manifold was designed to sample air 3 feet off the starboard side of the ship to avoid deck circulated air however could not be successfully installed. The original intakes have been used. We have not seen any issues so far with ship borne contamination.

Figure 7: Tekran 2537 ambient mercury vapor analyzers with pump unit

The first major atmospheric mercury depletion event recorded occurred on February 29th and preliminary data suggests that the reaction may be taking place on particulate surfaces; this may be due to the fact that this is where the BrO is absorbed, and thus the particle surface is used as a reaction site in which the GEM is converted to RGM. It is also possible that the RGM is photoreduced back to GEM directly from the particle surface without ever being deposited. The following graphs show the initial data; Figure 3 shows GEM measured from the 1130/1135 speciation unit, ambient air with a

2537, as well as the Hg_t with the pyrolysis unit. Figure 4 and Figure 5 show the two initial depletion events in detail including calculated values for coarse particulate mercury (Hg_t – GEM) showing the role of atmospheric particles during the events.

GEM measurements are done with a resolution of 1 every 5 minutes on two separate Tekran 2537 instruments. Due to the lesser concentrations of RGM and Hg_p the measurements for these parameters are thermally desorbed and analyzed by one of the 2537 units every 2 hours. Hg_t measurements are also conducted at a resolution of 1 every 5 minutes on a separate 2537 unit.

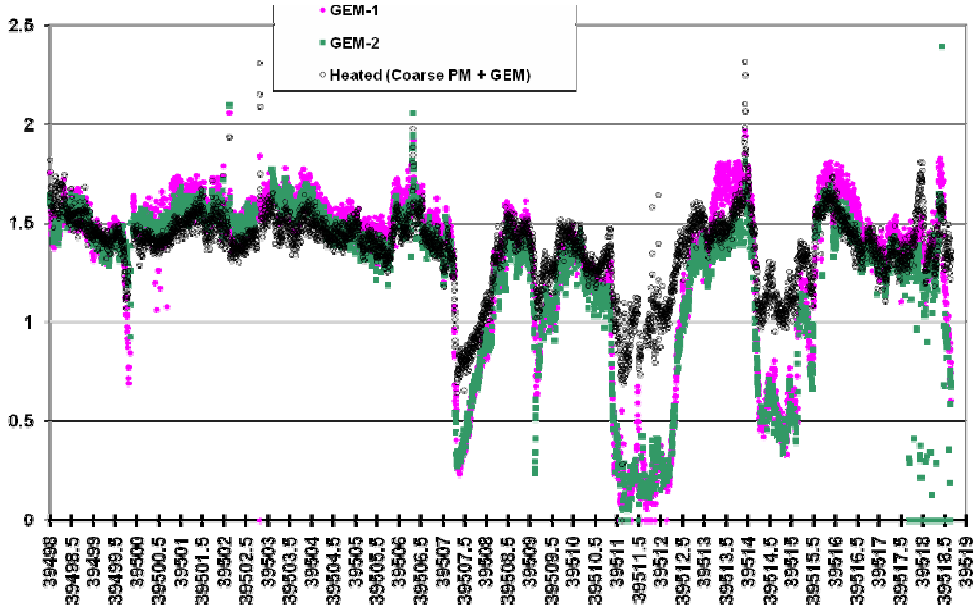

Figure 8: Gaseous Elemental Mercury

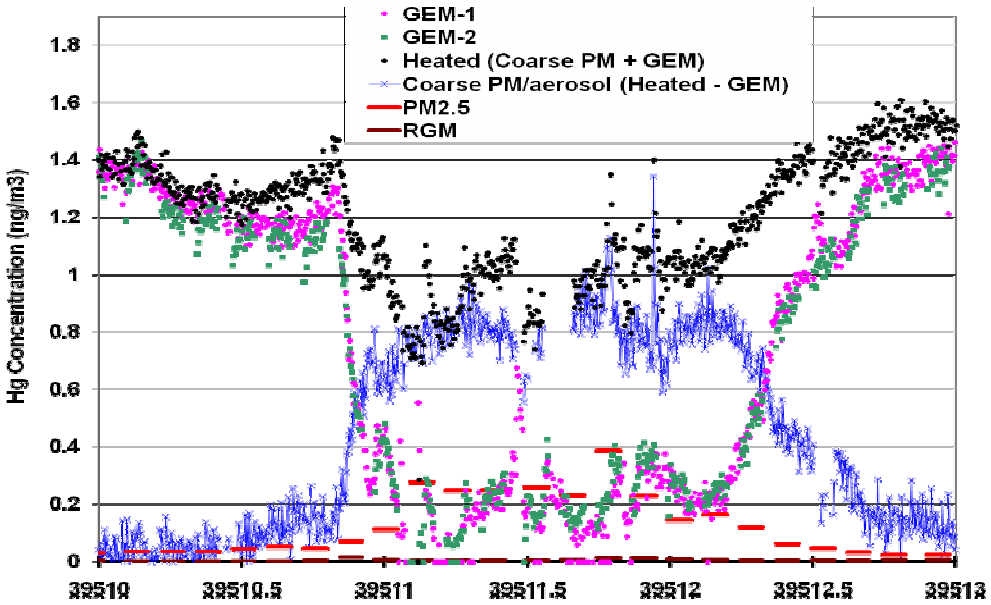

Figure 9: Depletion Event 1

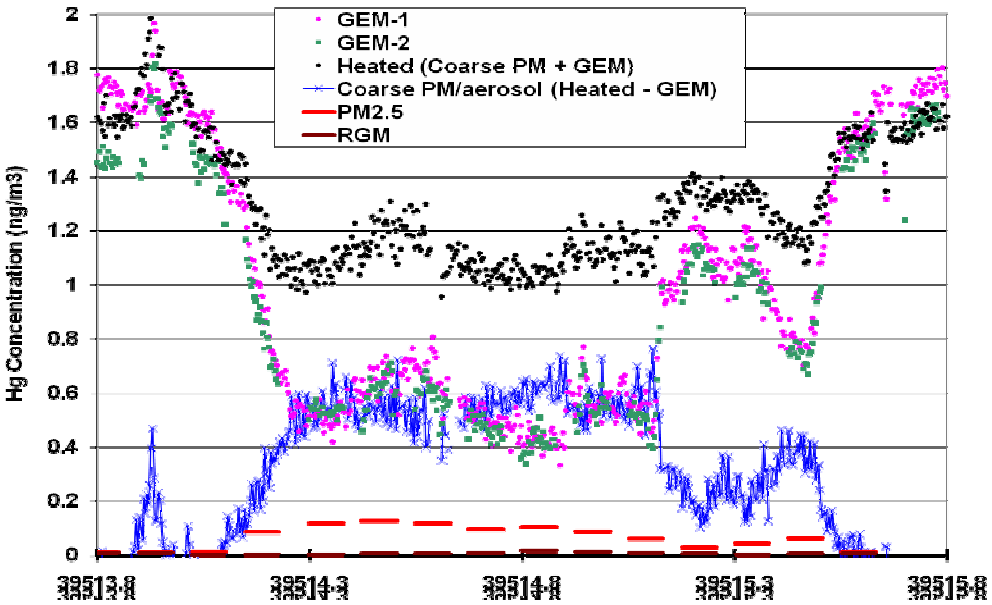

Figure 10: Depletion Event 2

Dissolved Gaseous Mercury

A system has been developed to measure dissolved gaseous mercury (DGM) in surface waters collected from either a niskin or the sea water sample line which has been installed directly into the PILMS laboratory. The system uses a specially designed vessel in which mercury free air generated by a zero air generator is bubbled through the sample and then measured by a Tekran 2537B unit. The zero air is purged through the vessel for 50 minutes in order to recover a high portion of the DGM in the 1 liter of sample water.

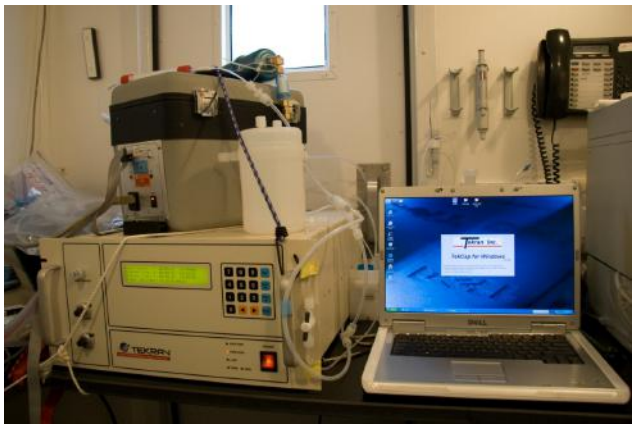

Figure 11: DGM measurement system in the PILMS laboratory

The initial data shows results typically between 150 and 40 ng/m^3 of water. Samples have been taken from open water, at station under thicker ice as well as at depth. Collection comes primarily from the sea water intake line in the lab, however samples collected from the niskin and rosette have also been analyzed as comparison and show no significant differences.

Sample	Date	Wind speed (kt)	Conditions	Result (ng/m^3)
SW 8	3/1/2008	2	In lead, sample line	107.500
SW 9	3/1/2008	3	In lead, niskin	99.651
SW 10	3/2/2008	17	Near lead, under ice	67.095
SW 11	3/2/2008	18	Near lead, under ice	89.658

SW 12	3/2/2008	18	Thick ice, lead frozen over	158.757
SW 13	3/3/2008	10	Open lead, very thin ice, AMDE, sample line	88.878
SW 14	3/3/2008	10	Open lead, very thin ice, AMDE, Niskin	99.529
SW 15	3/3/2008	12	Open water, Niskin	105.986
SW 16	3/5/2008	18	Under thick ice, no visible open water	95.484
SW 17	3/7/2008	12	Open leads ~ 1km, AMDE, Sample line	38.075
SW 18	3/7/2008	6	Open leads ~ 1km, AMDE, Sample line	58.411
SW 19	3/8/2008	22	Open leads ~1km from ship, sample line	58.188
SW 20	3/8/2008	3	Open leads ~1km from ship, sample line	89.819
SW 21	3/9/2008	15	Open water, from niskin	72.3450
SW 22	3/10/2008	0	Under thick ice, no open water visible	86.615

Biotic Sampling (HCH, mercury, stable isotopes) (Burt, DeLaronde)
The main purpose of this study is to link physical and biological processes to mercury levels in the food web and to target the pelagic food web biomagnification and bioaccumulation of HCH and mercury with stable isotopes and fatty acids. Thus, all biological samples collected will be measured for HCHs, total mercury and MeHg along with stable isotopes to place organisms into their associated trophic levels.
Biological samples were collected every 1-3 days. Various zooplankton families were collected using the vertically towed Tucker net (mesh size 500 µm) from the moonpool. Zooplankton was sorted by species where feasible, by genus or family otherwise and placed into plastic vials and Whirlpak bags and frozen until they can be shipped to Winnipeg where they will be analyzed for HCH, THg, MeHg, stable isotopes and fatty acids. Common species found were *Calanus* sp., *Euchaeta* sp., *Sagitta* sp., *Themisto* sp., *Ostracoda* sp., Cnidarians, Ctenophores, and Polychaetes. Some less common species found were *Cleone limacina*, *Hyperoche* sp., Euphasiids, *Pandalus* sp., and a couple of lucky arctic cod juveniles.
Algal samples were taken in conjunction with zooplankton hauls and preserved with lugol's. Alga was also collected from the surface water and filtered onto pre-combusted and weighed glass fibre filters (GF/F), in series. Surface water was also filtered for chlorophyll a and dry mass. These were also frozen, and will be shipped to Winnipeg for further analysis.

Stations D19(x8), D20, D22, D23, D25(x2), D26(x5), D27(open water) and D29(x5) were sampled for a total of 24 zooplankton hauls.

Monitoring and Speciation of Mercury (Hg) in the Arctic Atmosphere during the Mercury Depletion Event (Lee)

Introduction
Mercury (Hg) in the air is an interesting and important chemical species. It is one of the toxic metals exist in the atmosphere that we breath. When deposit into the ocean water, it can eventually bioaccumulation all the way up to the top of food chain - Human. The initiate for this work is to collect as more scientific data as possible in order to understand the nature of Arctic atmospheric chemistry. Speciation of Gaseous, Particulate and Reactive Mercury can provide us more detail of the chemistry picture. Therefore, it is important to understand the chemical processes influencing the concentrations of mercury in the Arctic atmosphere.

In this paper, we present results from the monitoring the airborne mercury in the Arctic atmosphere during the spring-time Mercury Depletion Event (MDE). Different instrumentations were set up for analyzing the various Hg species at the Arctic atmosphere. The purpose for this study work is to find out the Hg balance at the well know phenomena of MDE exist in the Arctic atmosphere.

Equipment and Methodology

1. Ambient air for Total Gaseous Elemental Mercury (GEM) determination was collected using a real time Hg analyzer (Tekran 2537) operating at 1.5 L/min flow rate for a 5 min average reading. A Teflon filter (47mm Sartorius PTFE, 0.2µm pore size) was used for separated the particulated and aerosol from the ambient air for the total GEM measurement in the Arctic atmosphere. This filter was placed on the back of the instrument sampling inlet line. An Arctic pyrolyser (Tekran 1105-P) sampling unit was installed on the outside next to the edge of the ship. Figure 1 illustrates the unit contains a sampling inlet head with two sampling lines running through the system: (a) Ambient air without any heating for the measurement of the total GEM; (b) Pass through a furnace that was heated up to 900^{o}C by the quartz bead for converting most of the coarse particulated/aerosol into gaseous Hg. We do not know the exactly size cut from the sampling inlet of the pyrolyser. Based on the design of the inlet head and only draw 3 lpm of flow, it is close to coarse airborne size. Figure 2 provides a close up image of the sampling inlet head. We assumed the pyrolyser heated at 900^{o}C converted and measured the total of the GEM + Hg bounded into the coarse PM or aerosol.

Figure 1. Sampling head for the Arctic Pyrolyser (right side) and for the Mercury speciation system (left side)

Figure 2. Pyrolyser sampling inlet head

2. Another Mercury speciation sampling system (Tekran 1130/1135) was installed for the speciation of Gaseous, Reactive and Particulate Hg. The sample inlet contains an impactor which provide a particle size cut of 2.5µm (PM2.5) at 10 L/min flow rate (Figure 1). It collects ambient air at 2 hrs sampling mode for GEM measurement, and then followed by one hour desorbing mode for reactive gaseous and particulate Hg determination. Figure 3 presents the whole sampling system of both the Arctic Pyrolyser (bottom) and the Mercury speciation system (top).

Figure 3. Sampling systems for the Arctic Pyrolyser (bottom) and the Mercury Speciation system (top).

3. Sampling were collected every 5 minute average from Feb 02 to Mar 11, 2008. The measurement site was on the front starboard side of the Amundsen icebreaker. The ship was moving around between the ice of the Beaufort Sea and Amundsen Gulf. An intensive quality control program was implemented to maintain the accuracy and precision throughout this project. This included periodically using standard Hg vapor calibration (Tekran 2505), internal permeation Hg source calibrations at regular intervals, standard addition every 73 cycles, and baseline monitoring.

Results and Discussion

Figure 4 displays the different of Hg species concentration throughout the study period. GEM-1 is the measurement of ambient air without heating from the pyrolyser, while GEM-2 is the sample collected from the mercury speciation system. Result for the two different GEM instrument were matching with each other very closely. The pyrolyser heated coarse PM/aerosol concentration was following both GEM value during non-MDE. Three major MDEs were identified between the period Feb 29 and Mar 08, 2008.

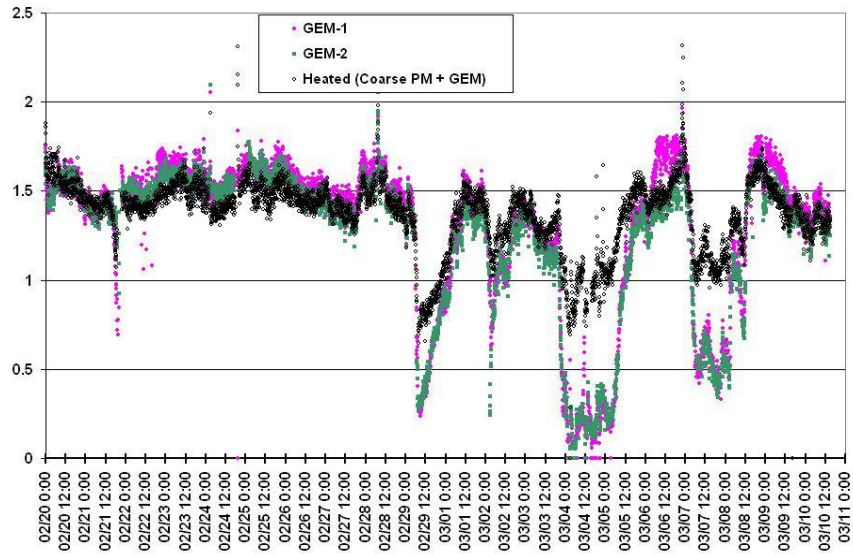

Figure 4. Hg concentration from Feb 02 to Mar 11, 2008

Figure 5 is a plot of the 3 days MDE from Mar 03 to Mar 06 2008. Three parameters were added on this plot (a) the pyrolyser heated value minus the GEM-1 value which is equal to the Hg bounded into the coarse PM or aerosol; (b) Hg in PM2.5 from the Hg speciation unit; and (c) gaseous reactive Hg from Hg speciation unit. The Hg bounded onto the coarse PM/aerosol indicated a very good mirror image of the gaseous Hg depletion throughout the whole MDE period. The beginning and ending stage of the MDE demonstrates a very quick partition reaction rate between Hg bounded coarse PM and the GEM. The chemistry between two phase partitioning is so rapid indicate once MDE finished the GEM will be shift back to the gaseous atmosphere. The Hg in PM2.5 follow the coarse PM/aerosol pattern rise up during MDE further proves the partitioning between gaseous and the fine aerosol phase. Figure 6 shows another MDE from Mar 7 to Mar 8 2008 reveal the same pattern with a small scale of Hg depletion. The Hg concentration bounded onto the coarse PM did not rise up to the level before the depletion occur mean there is some GEM still need to be account for. The reminder of the GEM most likely is partition into ocean sea, ice and snow surface.

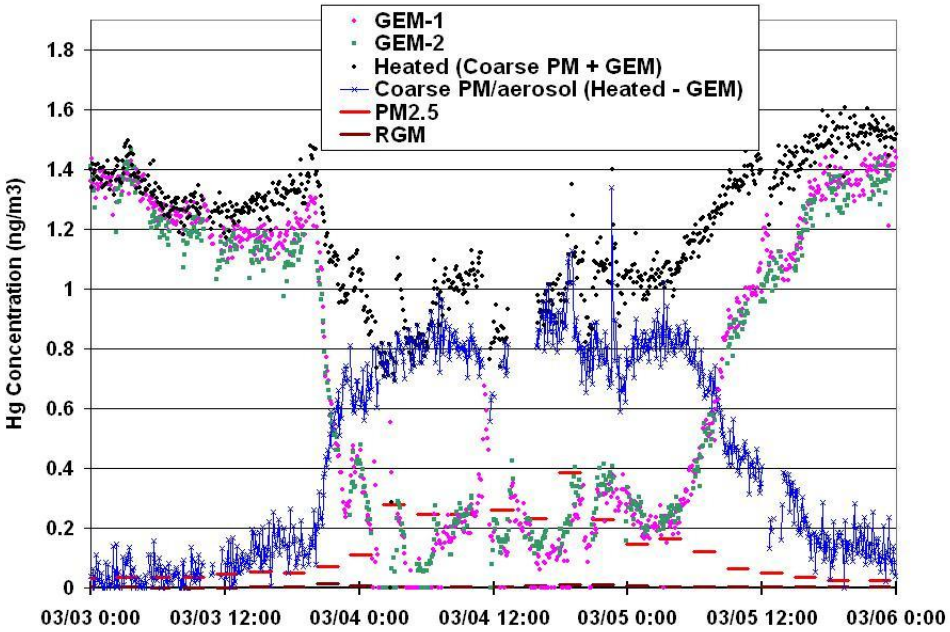

Figure 5. MDE from Mar 03 to Mar 06, 2008

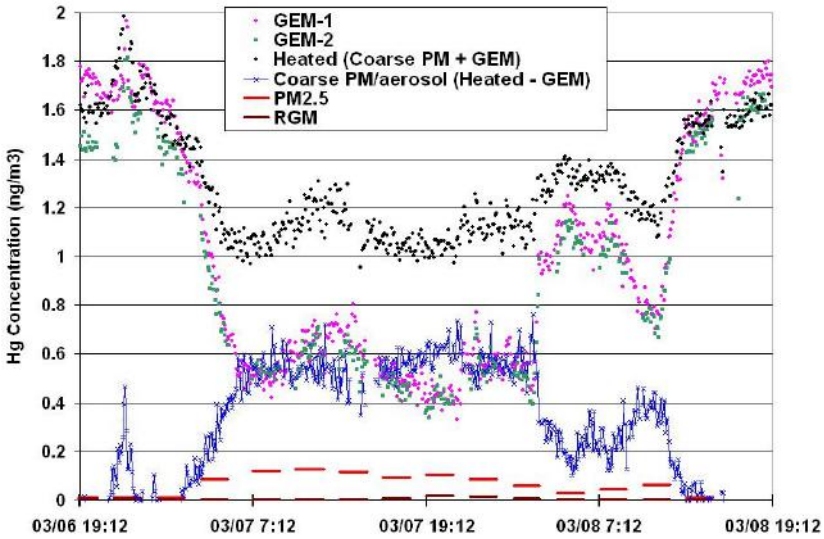

Figure 6. MDE from Mar 7 to Mar 8, 2008

In summary, during the MDE gaseous Hg was partition into the coarse PM/aerosol phase at a very fast reaction rate. More than 50% of the GEM was involved in the partition reaction. The chemistry reaction could be appears at the surface of the aerosol. As the MDE end the Hg that absorbed onto the surface of the aerosol immediately release back into the gaseous atmosphere. Further study of the Hg content in the sea, ice and snow at the time before, during and after the MDE may provides more detail picture of the total Hg balance system in Arctic atmosphere.

3. 2008 International Schools on Board - Field Program #1

March 2-15th, 2008 – Onboard Leg 6B

submitted by: Lucette Barber, Program Coordinator

Schools on Board is an outreach program of ArcticNet and the IPY-CFL study, used to promote Arctic sciences in high schools across Canada and abroad. The field program takes high school students and teachers on-board the CCGS Amundsen where they are integrated into the activities of the various science teams conducting research in the Arctic. It blends adventure, curiosity and exposure to create an energized learning environment and provides opportunities for scientists to share their passion for science and research with students – both on the ship and in classrooms. The multidisciplinary nature of the field program demonstrates the breadth of opportunities that are available to aspiring young researchers and technicians. Face-to-face interactions with scientists of all levels (masters, PhD's, researchers, CRC chairs) and access to state-of-the-art scientific instrumentation onboard the Canadian research icebreaker are the focus of the on-board field program. To extend the outreach beyond the field program, experiences of those chosen to participate, are shared with fellow classmates, family members and communities through a series of presentations that are delivered by the participant upon their return home.

The first of 2008 Schools on Board Field Program experienced a very successful year on-board Leg 6B of the Circumpolar Flaw Lead system study. As part of our commitment to education and outreach for IPY, this year's field programs include collaboration with international research partners and schools. Our 14 spaces for this first of three field programs, were filled by 7 students; 5 teachers; and 2 program leaders from the following schools and agencies:

USA - Ocean Research College Academy **-** University of Washington - (1 student; 1 teacher);
CHINA - Qingdao Middle School #39 - Ocean University of China - (1student; 1 teacher);
UK - West Kirby Grammar School - Proudman Oceanographic Laboratory - (1 student; 1 teacher);
SPAIN - Fredric Mistral/Tecnic Eulalia, Instituto de Ciencias Del Mar - (1 student; 1 teacher);
CANADA - Inuksuit School, Nunavut, (1 teacher and 1 student)
CANADA - Sisler High School, Canada (1 student)
CANADA - Nellie McClung Collegiate, Canada (1 student)
Schools on Board – 2 program leaders; University of Manitoba

Participating schools were selected by collaborating research agencies. Individual participants were selected by their schools to represent their community and region on-board this very unique Arctic research experience. Participants met in Winnipeg where they proceeded to Inuvik. Prior to boarding the ship, participants engaged in cultural and community activities in both Inuvik and Tuktoyaktuk. These included: a visit to the Visitor Centre; activities at Samuel Hearne Secondary School; dogsledding, cultural tour in Tuktoyaktuk, and interactions with youth and community leaders in each community.

The group boarded the ship at 5:00pm on March 6, 2008 and immediately became integrated in the activities of the CFL science teams. The program included science lectures, lab activities and fieldwork. Details of the on-board program are posted on the IPY-CFL website (www.ipy-cfl.ca). Daily dispatches including a report, photos and ship location were sent to both, IPY-CFL, and ArcticNet central to be posted on their websites. This two-week adventure into Arctic research exposed students and teachers to the research objectives and methods of numerous science teams representing a number of research disciplines from institutions across Canada and abroad. See attached table.

In addition to hands-on research activities the program included information and sessions on various aspects of climate change in Canada's North, including local knowledge, art, culture, history, and politics.

Outreach
Based on participant and scientist evaluations, activities of the Schools on Board program were successful in raising the awareness of the program on two levels:

1. Increasing awareness of the Schools on Board program and its educational objectives
2. Increasing awareness of the IPY-CFL program and its scientific objectives

Website & dispatches
The primary communication tool for the program was the webpage hosted on the CFL and ArcticNet websites. These sites were used to deliver program details and relevant application information. The site was a very effective tool, as it also contained all of the necessary science information relevant to the science project and the Amundsen. During the field program, participants submitted daily dispatches (March 5-13th, 2008) to the CFL website and the ArcticNet Expedition logbook. These sites included text and pictures describing daily activities and interactions between scientists and participants. They allowed schools, teachers, friends, and families, to share the experience, as well as provided visitors to the website (general public and other scientists) with detailed information of this outreach initiative.

Live from IPY event:
On March 12, we went Live from the Amundsen to participate in an international conference call organized by PolarTrec (University of Fairbanks) in conjunction with International Polar Day – Changing Earth. This web-based conference call included presentations Live from the Beaufort Sea aboard the CCGS Amundsen, Live from McMurdo Dry Valleys in Antartica, and Live from a North America test site for a Russian drilling project. Participants from various schools and universities from across North America and abroad listened to the presentations and asked questions of the presenters. Participation on board the Amundsen included the captain Stephane Julien, Gary Stern (chief scientist), Mathew Asplin and Dustin Isleifson (University of Manitoba), all Schools on Board students, teachers, and program leaders.

Presentations
One of the required outputs from the participants is the preparation and delivery of presentations to their schools and communities. Students prepared their presentation prior to leaving the ship. Teachers will be expected to share their new knowledge with teachers in their region, as well as assist S/B with the development of educational resources. Information on presentations delivered by participants will be collected in a School Evaluation at the end of the school year.

Media
Media continues to show an interest in the program. Our media activities will be recorded in the Schools Evaluation at the end of June. They include (but are not limited to):

1. Various newspaper articles and radio interviews prior to departure in each respective community
2. Interviews and ongoing media coverage onboard the Amundsen with Emily Chung, CBC
3. Interviews with NewsNorth – Inuvik
4. Interview with
5. Interview – CTV – TV – regional and national news
6. Daily dispatches appearing on school website in Spain
7. Article featuring student and the IPY-CFL study in one of Spain's national newspapers
8. Daily blogs on Everett Community College website (Washington, USA) file:///Schools%20on%20Board/Field%20Program/FieldProgram_2008/IPY%20-%20International_1/Outputs/ORCA_blogs.html
9. Radio interview – CBC – Radio – Morning Show with Terry McLeod

In conclusion, this first 2008 International Schools on Board Field Program was a great success. The international perspective fulfilled our mandate to broaden our outreach activities on an international scale during IPY. The overwhelming positive feedback received from all stakeholders (students, teachers, schools and scientists) indicates that this program is welcomed in both the science and education communities.

Leg 7

13 March – 24 April 2008

edited and compiled by Tim Papakyriakou and David Barber (Chief Scientists)

1. General overview

1.1. Introduction

Leg 7 of the CFL project was succefully completed on April 24. The science plan allowed for several drift sites over the 6 week leg. In the first half of the leg (7A) the science teams conducted some drift site sampling and then secured the ship into thick FY ice south of DeSallis Bay. The mid leg crew change was done at this location. The ice here remained stable for about 1 week then broke loose and began to drift towards Banks Island. The Amundsen extacted from this situation and went to a location SW of Banks Island. We had a successful visit by team 10 to the ship at this location. The meeting was part of the CircumArctic climate change workshop. The one day visit to the tour was highlighted by a crack separating most of the visitors and science crews from the ship. We continued with draft sampling over the next week and finally settled into a large older FY floe in the middle of Amundsen Gulf. The second International Schools on Board program joined the ship at this location. The helicopter was delayed by about 10 days getting to the ship but was operational immediately after it arrived. Crew change to leg 8 went without a hitch.

1.2. Cruise maps and station identifiers

Yves Gratton acted as a 'keeper of station ID's on this leg. He produced a map showing the drift stations identifiers and has in his records a more complete description of the lats and longs of each drift station. Note that box coring may not be co-located exactly with other sampling as quite often we had to move the ship to do a box core; we did however keep the same station identifier.

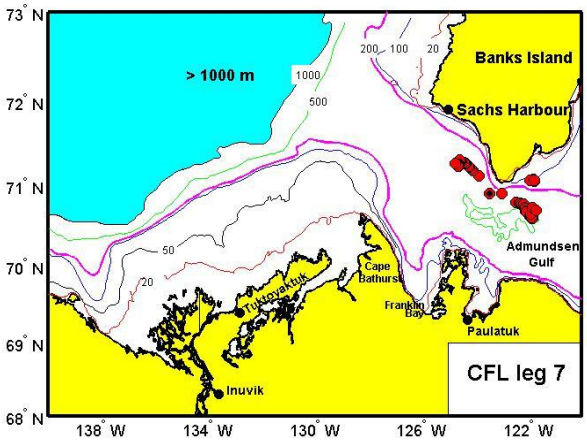

Figure 1. Drift stations completed during leg 7. Individual maps of these stations and their ID's are located in the Appendix of this report. Drift stations 29, 30 31, 33, 34, 35, 36, 37, 38, 40, 41 and 42 were successful completed on this leg. More details are available from Yves Gratton and in the appendices of this report.

1.3. Cruise schedule

Science operations on this leg consisted of on ice sampling, sampling through the moonpool and sensors which collected data while underway. The ships log should be consulted for specifics of what sampling occurred when, where and at what time. Note also that we were in the drift mode of the CFL project at this time so position locations at the beginning of a station stop are not necessarily and same as those in the middle or end of that same station.

2. Team reports

2.1. Team 1

PI: Yves Gratton (INRS-ETE, 490, Rue de la Couronne, Québec)
Participants: Louis Prieur, Shannon Nudds, Richard Marsden and Maria Sharatunova

2.1.1. CTD/Rosette

Objectives
Description of water masses and general circulation over a year in Beaufort Sea and Amundsen Gulf.

Materials
Physical parameters were recorded using a ship mounted RDInstruments Ocean Surveyor ADCP (150 kHz), and a rosette equipped with 24 bottles of 12 L each and the following sensors.

Photo	Item	Manufacturer	Type & Properties	Serial Number
	CTD	SeaBird	SBE-911 Sampling rate : 24 Hz	
	Temperature	SeaBird	SBE 3plus Range: -5°C to + 35°C Accuracy: 0.001	4204
	Pressure	SeaBird	Accuracy: 0.015% of full range	90584
	Conductivity	SeaBird	SBE 4C Range: 0 to 7 S/m Accuracy: 0.0003	2696
	Oxygen	SeaBird	SBE-43 Range: 120% of saturation Accuracy: 2% of saturation	0420
	pH	SeaBird	SBE-18 Range: pH from 0 to 14 Accuracy: pH 0.01	0444
	Nitrates	Satlantic	MBARI ISUS Range: 0.5 to 200 µM Accuracy: ± 2 µM	134
	PAR	Biospherical		4664
	SPAR	Biospherical		20147
	Fluorometer	Sea Point		2465
	Transmissometer	WetLab	Path length: 25 cm	CST-558DR
	Altimeter	Benthos		1061

Table 1: Sensors used on the Rosette

Method

For the whole leg, because of heavy ice conditions, the rosette was deployed from the Moonpool. CTD or Rosette casts were usually performed four times a day at 07h00, 11h00, 15h30 and 19h00. Twice (March 25 and April 1), we did a 13 hour non-stop CTD sampling. Water samples were collected on request. Here are a few typical examples of water sampling depths.

- *Nutrients* (Team 7; PI: Jean-Éric Tremblay): salinity of 33.1, 10, 20, 30, 40, 50, 60, 80, 100, 120, 140, 160, 180, 200, 250, 300 and every 100 m up to the bottom.
- *DIC* (Team 6; PI: Lisa Miller): salinity of 33.1, 10, 20, 30, 40, 50, 60, 80, 100, 120, 140, 160, 180, 200, 250, 300 and every 100 m up to the bottom.
- *Contaminants* (Team 8; PI: Gary Stern): 10, 25, 50, 100, 200 m and bottom.
- *Microbes* (Team 7; PIs: Carlos Pedros and Roxanne Maranger): "interesting" features in the O_2, NO_3, fluorescence, temperature and salinity profiles.
- *pH/alkanilitys* (Team 6; PI: Alfonso Mucci): salinity of 33.1, 10, 20, 30, 40, 50, 60, 80, 100, 120, 140, 160, 180, 200, 250, 300 and every 100 m up to the bottom.

Sampling region

We focused on the northern Amundsen Gulf, south of Banks Island.

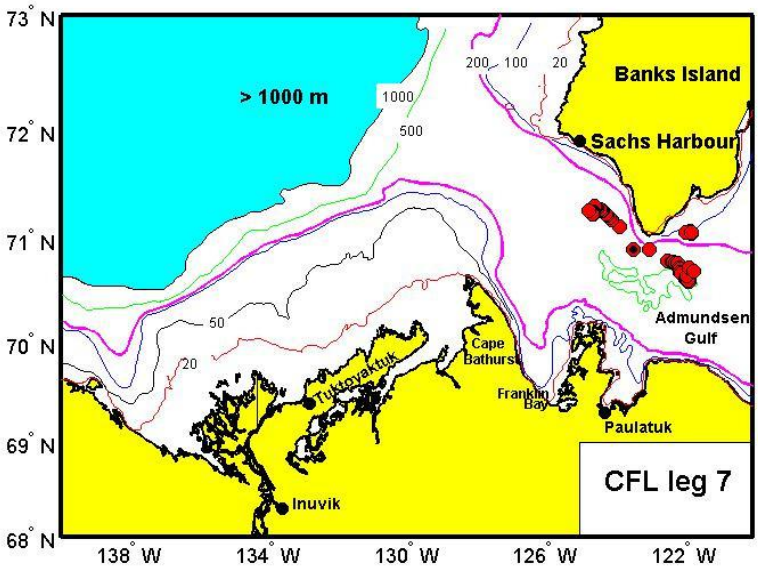

Figure 1: Location of all the rosette and CTD.

Probes calibration

Salinity: Samples were taken on many casts with small bottles of 200 mL. They were analysed with an autosal GuildLine, model 8400B. Its range goes from 0.005 to 42 and its accuracy is <0.002. The results were satisfying. The difference in between the salinity probe recordings and the samples was around 0.033.

pH: Tests were done using two buffers. The sensor is quite stable. Results are as follow:
Buffer 4.01 gave 4.09
Buffer 7.00 gave 7.45
Sea water is usually around pH=8, we can expect pH data to be a little over estimated.

Oxygen: Oxygen sensor calibration was performed using Winkler's method and a Mettler Toledo titration machine. Reagent Blanks were performed once, results show that chemicals are still good (m<4). We sampled oxygen on eight casts. Each time, we choose five depths of different oxygen concentration and sampled it three times. Results were really goods, the probe recordings and the samples were always pretty similar.

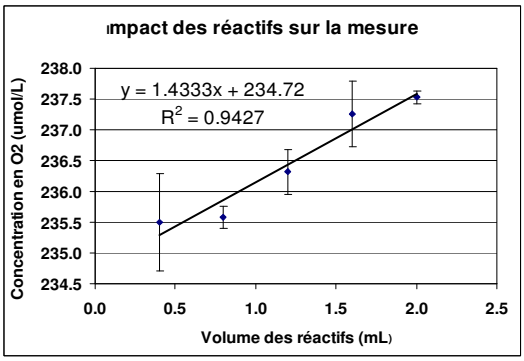

Figure 2: Reagents Blanks (m=1.4333).

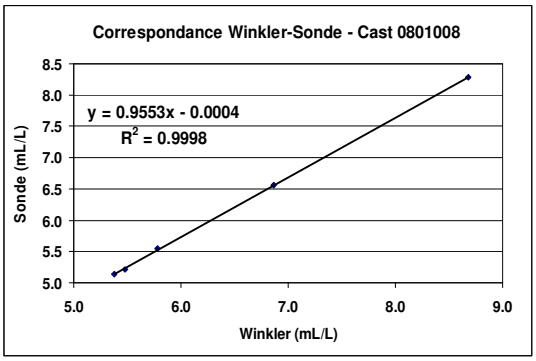

Figure 3: Relation between samples and probe recordings during cast #008 (m=0.955).

Problems

- **Sensors**
  We had pH problems between casts 036 and 055. We don't have nitrates data for casts 65, 66 and 67. We tried an ISUS filter on the nitrates sensor to try to remove the noise on casts 98 and 99: disaster. We changed the fluorometer settings from 0-150 µg/l to 0-50 µg/l. We had problems with the next four profiles (casts 109, 110,111 and 112), but everything came back to normal. We also had problems with the dissolved oxygen sensor and then the salinity. The pump was changed with no amelioration after cast 115. The connecting cable was the changed after cast 122° and everything went back to normal. Oxygen below 250 m from casts 116 to 122° should be ignored and salinity from casts 118 to 122° will have to be checked thoroughly. Thanks to Pascal Massot for fixing all the previous problems.
- **Bottles**
  Some bottles are leaking once in a while, which is a problem that had persisted for a few legs. Bottles number 4 and 5 were not closing all the time at the beginning of the leg. Sylvain Blondeau has repaired them.
- **ADCP:** It's something difficult to get data on the whole water column. This is most probably due to a lack of reflectors at depth. We were really careful and we removed the ice from under ship each time we sarrived on station.

Available data

All information concerning the Rosette casts are summarized in the CTD Logbook. It includes cast and station numbers, date and time of sampling in UTC, latitude and longitude, bottom and cast depth, comments concerning the cast and its name. An electronic Rosette sheet was also created for every single cast. It includes the same information than the CTD Logbook plus the sampling history of the cast. The weather information is written in every Rosette Log as well as in a meteorological logbook. For every cast, data recorded at the moment of bottle closure were averaged and recorded in the so-called 'bottle files'. Averaged data are those recorded between 3 seconds before bottle closure and 7 seconds after it. It includes the bottle position, time and date, pressure, temperature, salinity, light transmission, chlorophyll, oxygen, irradiance and pH measurements. All those files are available on the 'Shares'.

- Rosette sheets and the CTD logbook : Shares\Leg7\Rosette\logs
- Bottles files : Shares\Leg7\Rosette\btl
- Plots of every cast including salinity, temperature, oxygen, transmissivity, nutrients, fluorescence and irradiance : Shares\Leg7\Rosette\plots

A total of 132 CTD-rosette casts were obtained between March 14 and April 23, 2008. More information may be found in the files "Log_Book_0802.xls". Annex 1, below, gives the position of all the CTD casts.

Preliminary Results

We observed a mid-depth eddy between March 29 and April 1 (between casts 46 and 66). The eddy was centered at 80 m and possesses a recognizable dome salinity and velocity structure (Figure 5).

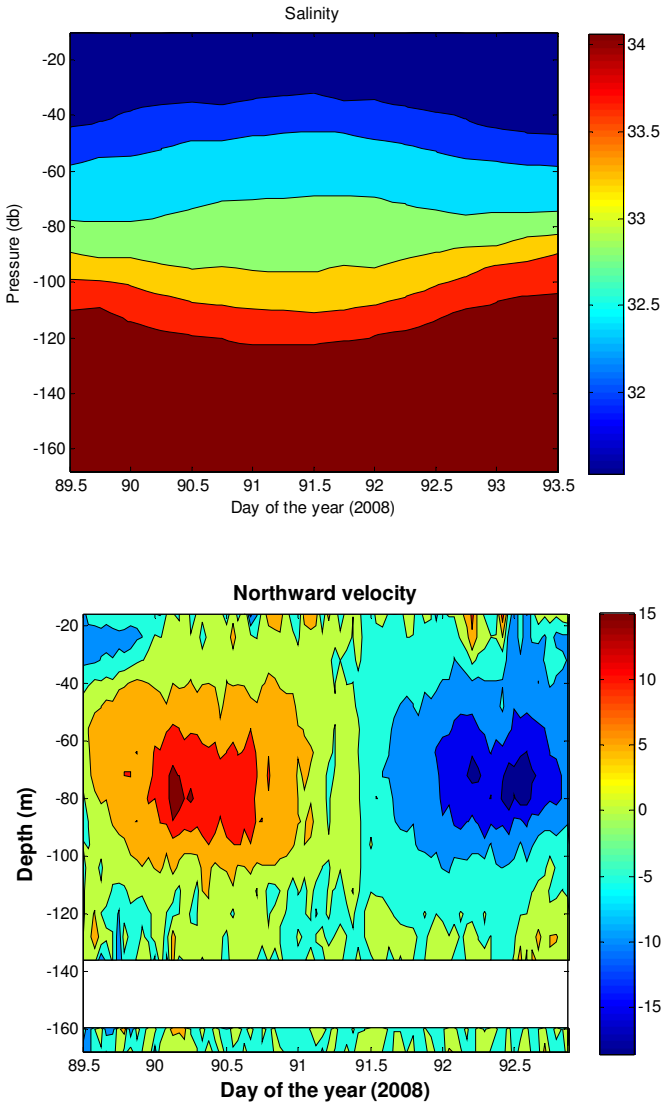

Figure 5: Salinity and velocity contours for the eddy observed between March 29 and April 1, 2008.

2.1.2. Self Contained Autonomous MicroProfiler (SCAMP)

Objectives

The SCAMP is a CTD type profiler (see figure 6). It samples at a frequency of 100 Hz (i.e. 100 times per second). It free falls at approximately 10 cm s^{-1}, resulting in a vertical resolution of approximately one (1) millimetre, down to a maximum depth of 100 m. The instrument measures the temperature and salinity fluctuations at the micro-scale in order to estimate the turbulent mixing occurring in the water column. To properly measure (as opposed to "estimate") turbulence we should also be measuring the velocity fluctuations. Unfortunately, we do not have velocity sensors (too expensive for

now). The current sensors on the SCAMP include temperature (three sensors), salinity (i.e. conductivity; two sensors) and fluorescence.

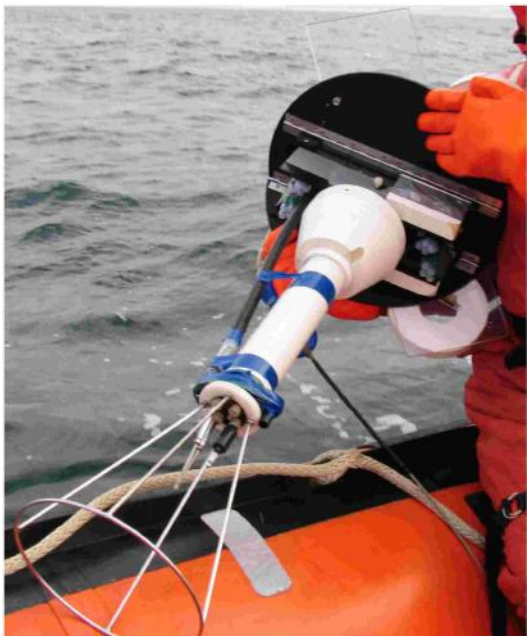

Figure 6: SCAMP in its summer quarters.

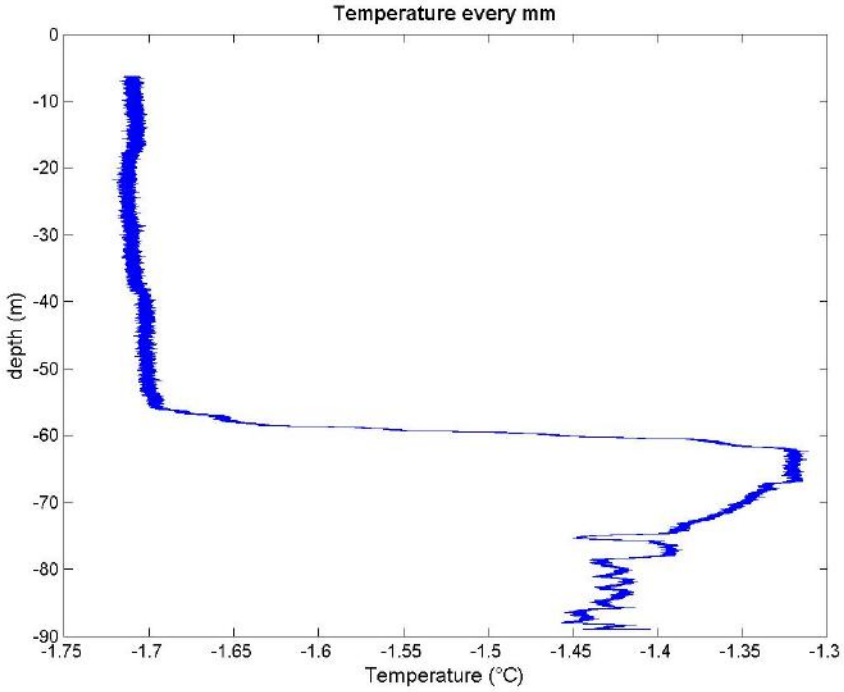
Turbulent transports and mixing are among the most important processes in natural systems. They are much more efficient and act much faster than purely diffusive (i.e. molecular) processes. By analogy with the molecular diffusive processes, turbulent mixing is often called “eddy diffusion”. The mixing energy is introduced at large scales, often by the wind at the sea surface and tides at the bottom. Turbulent mixing is called “eddy diffusion” because energy can be thought as being transferred from larger scales to smaller scales, i.e. cascading from larger eddies to smaller and smaller eddies until it reaches the molecular scale where it will be ultimately dissipated into heat. Studying turbulent processes will help us understand how the Mixed Layer (ML) if formed and how it evolves over daily, seasonally and yearly time scales. A better knowledge of the ML properties will help determine how the biological production is affected by the physical processes in the surface layer. A better understanding of the dynamics of the ML will improve our climatic forecasting abilities. Indeed, the mixed layer is the main buffer between the atmosphere and the ocean and it controls most of the heat exchange between the two. One of the major problems is that the ML is evolving hourly, making it very difficult to parameterize in larger numerical circulation models. A better understanding of the ML dynamics will improve the forecasting capacities of both oceanic and atmospheric models.

We encountered a lot of communication problems with the probe. The table, below, summarizes the basic information about the SCAMP profiles obtained during Cruise 0802, i.e. in CFL leg 7. More information may be found in the file “scamp_log_0802.xls”.

Station	Date (UT)	Time (UT)	# profiles	Profiling depth
2008 D38	2008/04/12	17:30:00	3	90 m
2008 D41	2008/04/22	17:00:00	1	90 m

Figure 7. High resolution temperature profile at station D41 on April 22.



2.1.3. Ice Camp

Team 1 planned study the boundary layer between the ice and the top of the ocean mixed layer. The mixing processes in this region have a big impact on the exchanges not only between the ocean and the ice but also on the phytoplankton living in the ice.

The instrumentation for the boundary layer turbulence system consists of three principal components as follows:

- 2 X 614 kHz RDI Acoustic Doppler Current Profilers (ADCPs)
- 2 X 10 MHz Sontek Acoustic Doppler Velocimeters (ADV).
- 2 X PME fast sample thermistor and conductivity probes (SC).

The ADCPs function separately while the ADVs and SCs are integrated into 2 boundary layer heat and salinity flux monitors (BLM). Data collection for the BLM is controlled through a Campbell 3000 data logger. The two ADCPs and the bound BLMs are mounted on aluminium frames and lowered through the ice so the instruments intrude the water column to just below the ice-water interface. The overall sampling set-up is shown in figure 8.

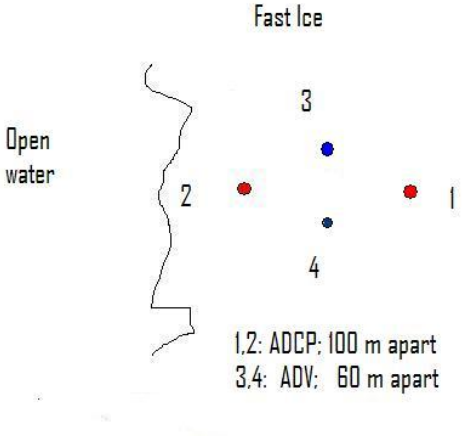


Figure 8: Ice camp ADCP and ADV set-up

ADCP System
The ADCP system consists of two instruments. The objectives are twofold:

1. one ADCP will be set to high resolution mode - mode 11 with a depth resolution of 25 cm sampling at 1 Hz the data will be analysed to determine the turbulence properties as a function of depth. Typically the instrument will sample to 7 m below the ice-water interface.
2. the second ADCP will be used to monitor the larger scale water properties (i.e. internal waves and solitons. The instrument will be set to mode 1 with a one minute sampling interval with 2.0 m depth bins. Typically the instrument will be able to sample to 25 m below the ice-water interface

Boundary Layer Conductivity and Temperature Monitor (BLM)
The purpose of the BLM is to obtain eddy correlation estimates of turbulent salinity and temperature flux at the ice-water interface. There are two BLM consisting of three distinct systems:

1. A Sontek point velocimeter (2 units)
2. A PME conductivity and Temperature probe (2 units)
3. A Campbell 3000 Data logger that will log data from all four sub-systems simultaneously.

All the equipment was put together for the first time (a lot of new instruments) and tested successfully in the outside rosette control room. Unfortunately, the ice conditions prevented us from mooring them at the proposed Ice Camp location.

2.1.4. List of Moonpool operations

This section contains a simple list of moonpool operations in CFL0802 (leg 7).

2.2. Team 2

2.2.1. Ice Dynamics

PI: David Barber (CEOS, University of Manitoba)
Participants: Klaus Hochheim (Research Associate, CEOS, University of Manitoba),
Andrea Rossnagel (MSc Student, CEOS, University of Manitoba),
Monika Pucko (PhD student, DFO and CEOS, University of Manitoba)

General Ice Conditions

Leg 7a started with the ship stationed in a "fast ice" location SSW of De Salis Bay, Station D33, within medium first-year ice (FYI) where the ice thicknesses were approx. 120-150 cm with a band of younger ice adjacent (30-70cm thick). This site remained in a fixed location until April 3, when the site had to be evacuated. The first half of leg 7 was dominated by a high pressure system, clear skies, and relatively calm winds. The stations after April 3 were all mobile as ice was being flushed out of Amundsen Gulf. A ice bridge (Figure 1b) remained in intact till the morning of April 14.

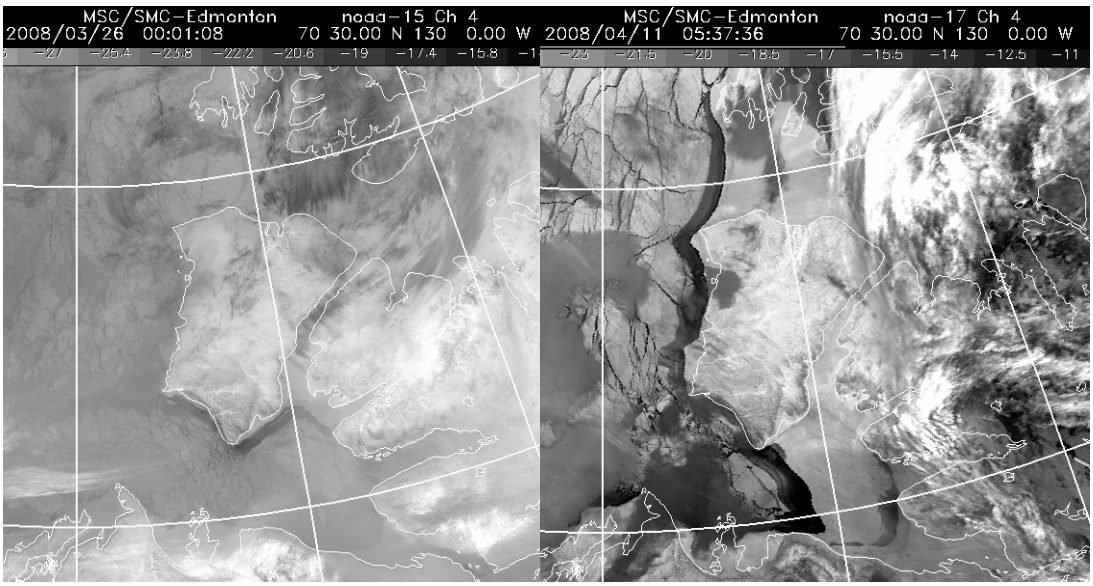

Figure 1. A) AVHRR image from March 26, 2008; B) April 11

Physical Sampling

The Team 2 CFL ice raid program continued throughout Leg 7a following the protocol that was previously established in Leg 5. We have termed this sampling "Drift Mode Sampling." The goal is to obtain physical and microstructure measurements of the snow and sea ice, and for twice-daily sampling to occur at the same time as the passage of a train of arctic monitoring satellites at 9:30 and 3:30pm. We continued the drift mode sampling protocol, protecting our EM scanning site with a fence, and performing twice-daily sampling in areas indicative of the area being scanned. There were chances to visit the flaw lead and consequently examine thin and newly forming ice and therefore samples were taken on an opportunistic basis to optimize our data collection

The ice surface condition was recorded and site photos were taken. The nature of ice coring and snow pit work depended on how many days we had been at that site, but in general we followed the sampling protocol outlined in Table 1.

Table 1. Drift Station Physical Sampling Protocol.

DAY	ICE (AM)	SNOW (AM)	ICE (PM, TOP 40 CM ONLY)	SNOW (PM)
Day 1	T, Sal, VMS, D	T, Cap, SGA, D, depth, Sal	T, Sal	T, Cap, SGA, D, depth, Sal
Day 2	T, Sal	T, Cap, SGA, D, depth, Sal	T, Sal	T, Cap, SGA, D, depth, Sal
Day 3	T, Sal, D	T, Cap, SGA, D, depth, Sal	T, Sal	T, Cap, SGA, D, depth, Sal
Day 4	T, Sal	T, Cap, SGA, D, depth, Sal	T, Sal	T, Cap, SGA, D, depth, Sal
Day 5	T, Sal	T, Cap, SGA, D, depth, Sal	T, Sal	T, Cap, SGA, D, depth, Sal
Day 6	T, Sal	T, Cap, SGA, D, depth, Sal	T, Sal	T, Cap, SGA, D, depth, Sal
Day 7	T, Sal	T, Cap, SGA, D, depth, Sal	T, Sal	T, Cap, SGA, D, depth, Sal
Week 2 at site	Repeat from day 1	Repeat from day 1	Repeat from day 1	Repeat from day 1

Ice: T = temperature profile (T = core temperature profile, Sal = core for Salinity, VMS = core for vertical microstructure, D = core for density.
Snow Pits: T = temperature profile, Cap = capacitance plate, SGA = snow grain analysis, D = densit, Sal

In summary, we took ice cores twice per day for salinity and temperature profiles, with the 3:30 pm ice cores limited to the top 40 cm. A core was taken for vertical microstructure on day 1 as well as density. We also performed a twice-daily snow pit measurement according to our standard procedure. This includes temperature profiles, salinity profiles, capacitance plate measurements, and snow grain photos.

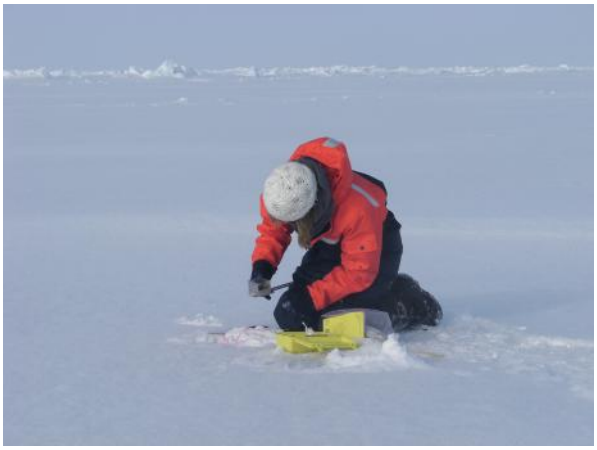

Figure 2. Typical snow pit measurement procedure.

Table 2. Ice Sampling Summary

DATE	STATION	SNOW	ICE TYPE	ICE MICRO
17-Mar-08 to 18-Mar-08	2008D29	Variable (5 – 14 cm)	First year ice (110-135 cm)	Vertical
19-Mar-08	2008D31	Frost Flower Collection	First year ice (28-55 cm)	Vertical

25-Mar-08 to 03-Apr-08	2008D33	Variable (5 – 38cm)	First year ice (135 – 153 cm)	Vertical
6-Apr-08 to 9-Apr-08	2008D36	Variable (2 - 13cm)	First year ice (70 – 160 cm)	Vertical
16-Apr-08 to 23-Apr-08	2008D41	Variable (4.5 - 72cm)	First year ice (128-140 cm)	Vertical

Ice sampling was not as regular (twice a day) in 7b due to fewer team members on board as well as flooding of EM sites during repositioning of the ship. Snow sampling carried on regularly with more sites being done.

Ship Based EM Measurements

EM measurements were conducted throughout Leg 7a in order to observe the interaction of electromagnetic radiation with various ice conditions. The collected data will be used in electromagnetic modeling studies and for calibration of satellite remote sensing data. The results of this study will allow for us to improve our knowledge of the temporal evolution of sea ice physical, thermodynamic, and electrical properties during the winter ice growth period.

Scatterometer

A fully polarimetric scatterometer system was operated at each station stop. The height of the instrument above the surface has been regularly measured and maintained in the operations log. Measurements from the ship were conducted with a sweep from -30° to 30° in the azimuth, requiring the 0° reference at a perpendicular line to the ship side. The variation in elevation was measured with sweeps in the elevation at 5° increments on the range 20° to 60°. Table 3 summarizes the scatterometer data collected during Leg 7. An infrared transducer (Everest, 4000L) was mounted on a rail near the scatterometer.

At the beginning of Leg 5B, we had noticed that sometimes the noise floor of the system would rise and therefore some of the radar returns would be lost in the noise and corrupted. This problem was not evident in Leg 7a, towards the end of 7b noise was evident, cables were cleaned and dry resulting in a clean signal. Operators of the instrument need to continue monitoring noise levels to ensure high quality data.

Table 3. Summary of scatterometer data acquired.

Ship-Based Radiometer (SBR)

Dual polarized radiometers operating at 37 GHz and 89 GHz with a 6° beamwidth were mounted about 12 m above the sea surface on the port side of the ship. The SBR conducted twice daily scans to correspond with our physical sampling program. The system was operated in a scan mode, changing the incident angle from 30° to 150° using 5° steps. During transit, the radiometers were kept at an incident angle of 55°. A network camera was used to monitor the surface conditions at a sampling rate of 10 s while in transit. The settings have not been changed otherwise. In addition, a hand-held camera is used at each site to provide more information on the surface conditions. A summary of SBR data collected is provided in Table 4.

Laser Profiler

The laser profiler was disassembled and put in storage during Leg 5, and thus was not operated during Leg 7.

Skippy Boat

The purpose of the skippyboat is to allow us to investigate several sites using the optical equipment on board, and still return to the sites to perform additional measurements and physical sampling. The skippyboat was de-winterized at the beginning of Leg 7b, and was used throughout the duration of Leg 7b.

Figure 3. Skippy boat in lead allowing scientists to sample water and do PAR and CTD measurements.

Coloured Dissolved Organic Matter (CDOM), Fluorescence of Dissolved Organic Matter (FDOM), Salinity and Oxygen Isotope ($\delta^{18}O$)

Dissolved organic matter (DOM) plays a major role in the ocean as carbon and energy sources for the microbial food web, and for consumers at higher trophic levels that feed on microbes or on DOM directly. The coloured fraction of this dissolved organic matter is a complex pool of autochthonous materials, derived from in situ photosynthetic activity and processed microbially, and allochthonous materials, that are rich in humic substances and largely derived from terrestrial environments.

This coloured dissolved organic matter (CDOM) is photochemically active and also influences the spectral underwater regime that in turn affects primary production. The composition and reactivity of CDOM in aquatic ecosystems are still poorly understood. The sources and dynamics of DOM are of special interest in the coastal Arctic Ocean. These environments receive inputs of freshwater from large rivers that drain arctic tundra and peatlands as well as subarctic boreal forest. To increase the understanding of this tracer we are coupling the sampling with $\delta^{18}O$ which is a conservative tracer of freshwater masses. It has been estimated that more than 25% of the world's soil carbon lies in these catchments, and there is concern about how ongoing climate change may mobilize these stocks and transport them to arctic seas. The carbon derived from arctic rivers appears to be a major source of terrigenous DOM to the deep ocean, and changes in the magnitude and composition of this material therefore have broader oceanographic implications.

Global circulation models predict that the arctic basin will experience greater and more rapid warming than elsewhere over the course of this century, and there is increasing evidence that global climate change has already begun to have significant impacts on permafrost degradation and terrestrial vegetation dynamics at high northern latitudes.

Water was collected onboard using the rosette from the moonpool. The ice was collected at stations D38. The water was collected at 10 m, 25 m, 50 m, 100 m and 180 m on contaminant (THg) casts.

Due to problems with the spectrophotometer Cary 50, the CDOM samples has been store at 4°C and measurements of CDOM will be completed at University of Manitoba.

Preliminary Results:
CDOM and FDOM analysis will be performed after the cruise in laboratories at the University of Manitoba. Stable isotope analysis of water and ice samples will be analyze outside of the university.

Table 5. CDOM and FDOM sample locations.

Date (mm-dd-yyyy)	Station (#)	Cast (#)
02-04-2008	2008D35	72

Atmospheric Sampling Program
The purpose of the atmospheric sampling program is to monitor cloud cover and cloud properties, upper level and boundary layer winds, temperature, and humidity.

All-Sky Camera
The all-sky camera system is used to take pictures of sky in order that percentage and type of cloud cover may be determined throughout the cruise. The Camera system did not function for the majority of the trip, due to power issues, those were resolved. The camera takes pictures every 10 minutes.

Ceilometer
The ceilometer is used to measure the height of the cloud layers above the ship. The ceilometer was fully functional for most of Leg 7, with the exception of about a week, were water from the ceiling destroyed the computer. New software was obtained and installed in a new computer. Backups wwere performed at regular intervals.

Atmospheric Profiling Radiometer
The profiling radiometer is used to continuously measure the temperature, relative humidity, and pressure within the atmosphere to a 10 km altitude . The profiling radiometer has been running smoothly, with only occasional crashing of the interface software on the laptop due to a memory leak. Data collection was not affected.

Radiosondes (weather balloons)
There were 6 balloon launches during Leg 7, most were launched towards the latter part of Leg 7 as the first half of the Leg Was dominated by a high pressure system. Balloon launches were conducted to correspond mainly with low-pressure depressions and cyclones, one was released in support of OASIS (ozone event).

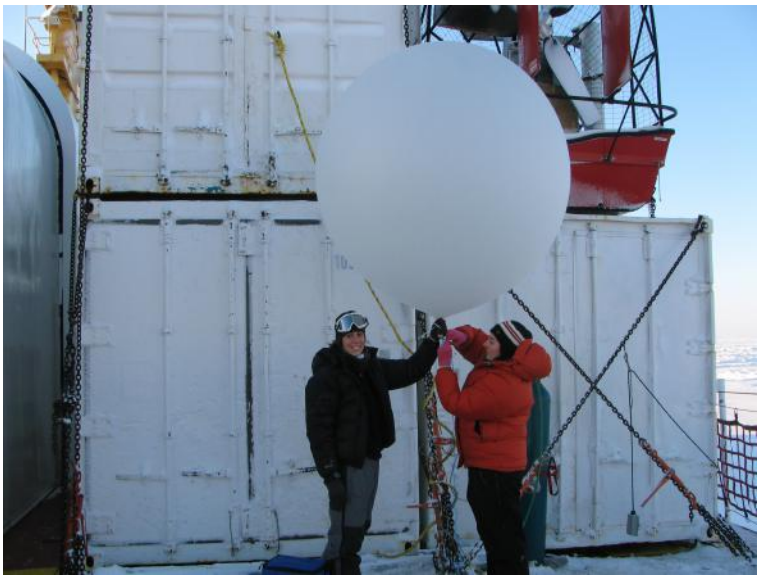

Figure 4. Attaching a radiosonde to a balloon for an atmospheric profile.

Table 6. Stations and dates of balloon launches.

Station	Date
2008D31	23/03/08

2008D41	16/04/08
2008D41	16/04/08
2008D41	17/04/08

Laser Precipitation Gauge

This instrument was not fully functional throughout Leg 7 but was for the second half of the leg. The instrument continues to run as per normal, and all data has been downloaded and archived.

Ice Motion Beacons

We deployed three ice motion beacons and will deploy a couple more before melt begins.

Table 7: Ice motion beacon deployments.

Beacon ID	Date Deployed	Location Deployed	Status
n/a	*/03/08	n/a	Active
19310	24/03/08	D33 Oasis reflector	Active
15000	5/04/08	n/a	Active
25590	17/04/08	2008D41	Active

Figure 5. Ice motion beacon installed in a first-year ice floe.

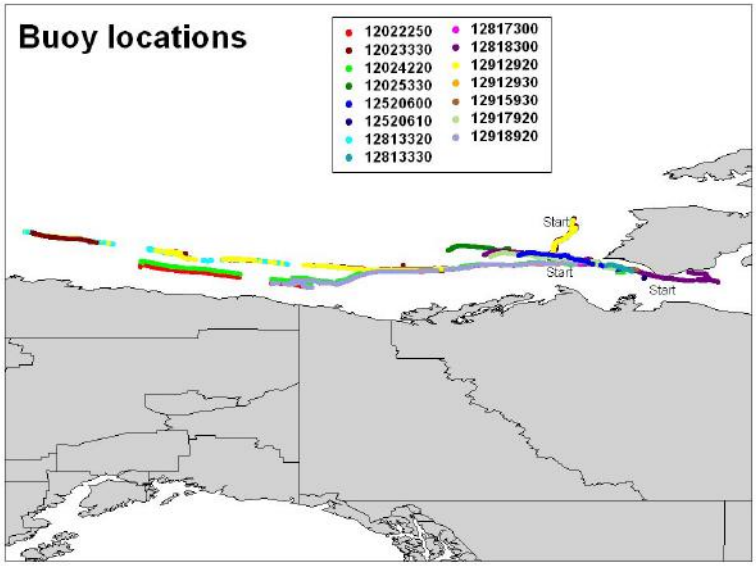

Figure 6. Ice motion buoy locations as of February 25, 2008.

Met-ocean MOBS Buoys
Two improved MOBS buoys were received, but have not been operated. The buoys are presently stored near and inside the benthic lab.
Met-ocean POPS Buoy

No POPS buoys were on the ship until the last week of Leg 7. There is also no fast ice camp so no POPS buoy has been deployed.

AVOS (Environment Canada MetObs System)
This system was operating normally, with the exception of a few glitches in data transmission that were worked out by the ship's electronics officer.

Light and Optical Measurements
The objectives of this experiment are to examine potential impact of sea ice (and related environmental parameters) on light intensity under various sea ice, snow and solar zenith angle regimes during the spring transition period (Legs 7, 8b and 9a). To address this objective we will be

measuring light fields (PAR) above and under the ice down to 60 m, albedo, snow properties (temperature, grain size, salinity) and upper ocean properties (conductivity and temperature) along with other relevant surface validation data. These measurements will be done in fast ice floes as well as in leads and the marginal ice zone. The ultimate intent is to extrapolate these observations/results to regional scales.

Figure 7. A CTD and PAR profile through the snow and ice

CTD (Conductivity, Temperature, and Depth) and PAR (Photosynthetically Active Radiation) profiles were done opportunistically with a focus on different snow and ice conditions as well as different times of the day. This is to see the affect of different snow and ice regimes on PAR in the water column below the ice. Profiles were also done through thin ice as well as open water between floes from the skippy boat and from the ice edge. Sampling was done at different times of the day to see the effect of solar zenith angle.

Snow pits including a vertical pit photo, and snow grain photos, density and salinity were done for the top, middle and bottom of each snow pack.

Snow Pits: T = temperature profile, Cap = capacitance plate, SGA = snow grain analysis, D = density, Dep = Depth

Moorings of PAR sensors were made and installed two times during the leg. One series was installed for a period of 24 hours and the second one for 5 days. In thick ice the strings of sensors went down to 30 m and along the ice edge and in the thin ice they went down to 50 m.

Downwelling and upwelling irradiance as well as under ice transmitted irradiance measurements were done every three days with a Licor quantum PAR sensor under low, medium and high snow depths in conjunction with Team 3. A table of sampling dates can be found in the Team 3 section of the cruise report.

Dive Program

Team 2 was involved in the dive program starting April 7, 2008. A Satlantic HyperOCR hyperspectral profiler was used for measurements directly under the ice, at 15 and 40 cm below, and for vertical 50 m profiles under the ice. The measurements were done under thin ice, 5 cm, to thick ice at 160 cm. After the measurements were completed for these sites, the snow was cleared and a second series of measurements were made without snow.

Figure 8. Hyper OCR about to be deployed at dive location

Table 8. HyperOCR data summary

Date	Type	Profile
April 7, 2008	Ice, thick (70 cm) and thin (5cm)	Profile to 50 m
April 8, 2008	Ice, thick (150 cm) and thin	Profile to 50 m
April 12, 2008	Ice, thick (130 cm) and thin	Profile to 50 m
April 18, 2008	Ice, thick (130 cm) with and without snow	Profile to 50 m
April 21, 2008	Ice, thick (130 cm) with and without snow	Profile to 50 m

2.2.2. EM ice survey

Participants: Scott Holladay (Geosensors ltd, Toronto, Ontario,
scottholladay@geosensors.com, April 3 – 17, 2008)
Simon Prinsenberg (Bedford Institute of Oceanography, Dartmouth Nova Scotia,
prinsenbergs@mar.dfo-mpo.gc.ca, April 3 -24, 2008)

Thursday, April 3 to April 16, 2008
EM sled work around the ship while stationed in the ice.
Waiting for the BO105 helicopter to arrive.
Ship moving towards Henson Point on southern tip of Banks Island (April 4-5)

Sunday, April 6, 2008
Testing sled over thick floe 165cm near ship and thin floe forward of ship 70cm.
Ice thickness transects to-from thin floe to ship.

Monday April 7, 2008.
Calibration line over thick floe, the line runs South to North, with the bag and lead (divers) on the south side where the ship was. Bags every 10m, snow every 2.5m.

	Snow (cm)	Ice (cm)	Snow+ice (cm)	Sled EM (cm)
S - #1	6	166	172	---
	3 - 3 - 1

	10 - 10- 5			
#13	6	160	166	164

Accuracy of snow depths is +/- 1cm

Tuesday and Wednesday April 8-9, 2008

Several lines along thick calibration floes (SIS 125) and then the thin floe north of the ship (SIS 126). Drilled holes along the thin floe calibration line. Line ended at lead used for second dive. Ice thickness in lead 10-15cm. Thin layer of snow had covered frost flowers and made a salty slush layer of 38ppt. Depth increased from ½ cm at North (location #1) to 1cm at location 15 and towards the lead. They are in small4-6cm mounts of up the 2cm. Sled rails flatten some of the flush so snow depth for Sled EM system is estimated to be ½ - 1cm.

Table below shows the thin floe ice thickness, first 15 done on Tuesday afternoon, then last 11 (7-18) redone on Wednesday morning. Total length of line to edge of lead is 174.8m. SIS File 128

Table with thin floe thicknesses line running N to S and holes at 10m intervals.

Hole #	Distance (m)	Ice (auger)	Snow*	Sled	Snow+ice
1	0	75	½	77	76
2	10	73	½	76	74
3	20	72	½	74	73
4	30	73	½	75	74
5	40	74	½	76	75

14	130	72	1	74	73
15	140	72	1	72	73
16	150	70	1		71
17	160	73	1		74
18	170	70	1		71
Edge (4.8m)	174.8	71	4 slush ice		72

Files sled numbers SIS 129 and 130 along calibration line plus two and from thin floe to ship.

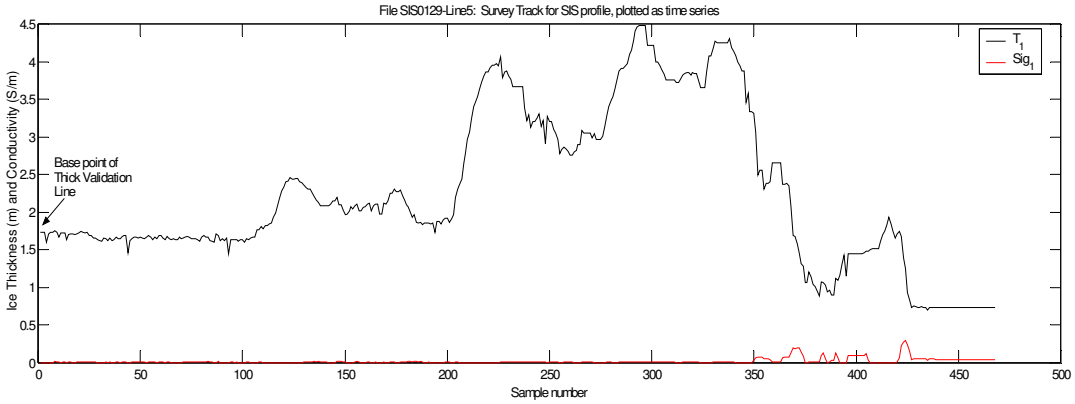

Figure above shows the ice thickness collected by the EM sled from thick floe (left) where ship was stationed to thinner flat floe area (right) where dive #2 was done. Ridge area between thick and thin floe sections follows the skido track (plotted below) used by others going from ship to thin floe section.

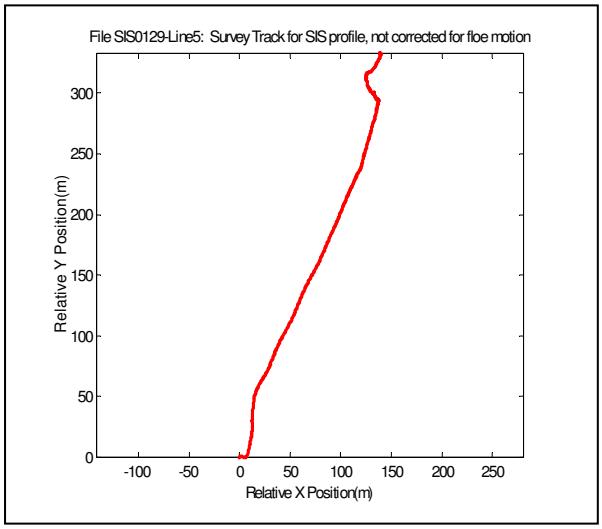

Figure on left shows the track along with the EM sled data was collected. Bottom of track is location where ship was located and top where thin floe section was located; total length of track around 350 meters.

Friday and Saturday April 11-12, 2008

Ship has moved to another floe and is staying here until Monday as thickness is fine to land both types of planes near the ship. Did the star auger check 125-127cm with 2-3 cm. Sled had 129cm. Collecting now general long lines with sled and returning to starting point to eliminate floe drift from GPS to geographical plots on floe. SIS 131 and SIS 132. Ship had moved to other end of floe. Afternoon to/from new to old ship location files SIS 133 and SIS 134.

Sampled thickness lines to the landing strip SIS135, the landing strip SIS 136 very homogeneous ice NW to SE, with NW end stopping into a small rubble area where thicknesses of runway increase to 150cm. Rest of the thicknesses ranged from 120 – 130 cm. Back to ship SIS 137. Went out on the ice in afternoon to sample several times the bare strip of ice used for light penetration and fluxes and diver's hole SIS 139. There appears to be a small affect from the wires at lead side and snow plow at the opposite side. Four out of six transects seem very clean of metal affects. Sample 75-115 (into floe 1.275m), 150- 180 (to lead 1.28m), 190-245 (into floe 1.256m), 310-345 (into floe 1.274m). SIS 141 and 142 are ice edge test files.

Sunday April 13-15, 2008 .

April 13 - Arctic Council visit and on-the ice affair when the floe split in two.
April 14 - Ship moving east, while helicopter is flying from Inuvik
April 15 - Helicopter here Pilot Michel Dube and technician Michel Gionet

- Captain Lise Marchaud and Dave Barber out in morning to find a better place to locate ship where another runway can be build. Paper work being done.
- Installed all the gear on the helicopter; an Radar altimeter plug was available for the EM system.

Helicopter EM survey (April 16-April 23)

Wednesday-Thursday April 16-17, 2009 - calibrations

Calibration line set out south of new ship position (two bags) (morning 16)
PIC#1 was flown and calibrated on April16 afternoon, with final flight Thursday morning. PIC #2 installed and tested over line and new constants inserted.
Two holes #1 near helicopter down wind from inside bag 128+5-6snow for 133-134cm and second hole along inside bag 126+5-6snow for 132-133cm. Sled sample up wind and down wind 134.5 and 135.1cm.
Second flight to SE then stopped at snow shower line; turned to East for 50km then back to ship into wind. Back by 17:00 and packed it in. Video 010-014 and GPR 715-719.
PIC File 109: ship at 122.11, 70.69 then line to SE 121.68, 70.42 then directly east to 120.55, 70.43 and back NW to 121.55, 70.62.

Friday and Saturday April 18-19, 2008 -survey

PIC file 110. To NWest for 50km and ended south of Banks Island, very windy and open water wind parallel to coast from NW. 123.8, 70.887. Turned 90deg to SW for 45km to 123.9 and 70.5 then turned towards the ship west to east line for 50km. Ship at 121.92 and 70.62 total line about 145km of alternating EM thickness and Video data.

PIC file 111. Out towards the north just east of Banks Island. First to NNW (121.99 and 70.754), then NNE to 121.63 and 70.953 and finally into Banks Island along North track121.59 and 71.18, very gusty wind and flat light caused to fly a bit higher than what we wanted. Open water along Banks Island and old flaw lead of 60cm thick turned into very rough ice along Banks Island and is now part of the land-fast ice. Total track north about 60km. Along Banks Island for 15km saw old runway on ice at 122.15 and 71.166. Criss-crossed rafted flaw lead with expected 60cm thick blocks to 122.26 and 71.19, then turned directly WSW to ship 50km. Total track length 140km.

Saturday -PIC file 112. Start at ship ~ 70.60, 122.80, due east to 70.44 121.1 then turn to south 70.07 120.77 and back to ship for about 140km track. Passing mostly over thick ice until on the return leg where thin ice is present all the way into the ship (from WSE for 60km).

PIC file 113. With two school-on-board teachers from Germany. From ship SSW to 70.14 and 122.55 then NW to 70.64 and 123.68 and back east to ship, 150km track.
Did four lines over small pack ice floe and thin lead SW of ship. Back ground between lines while doing video. Video on also over lead at 5-6m height.

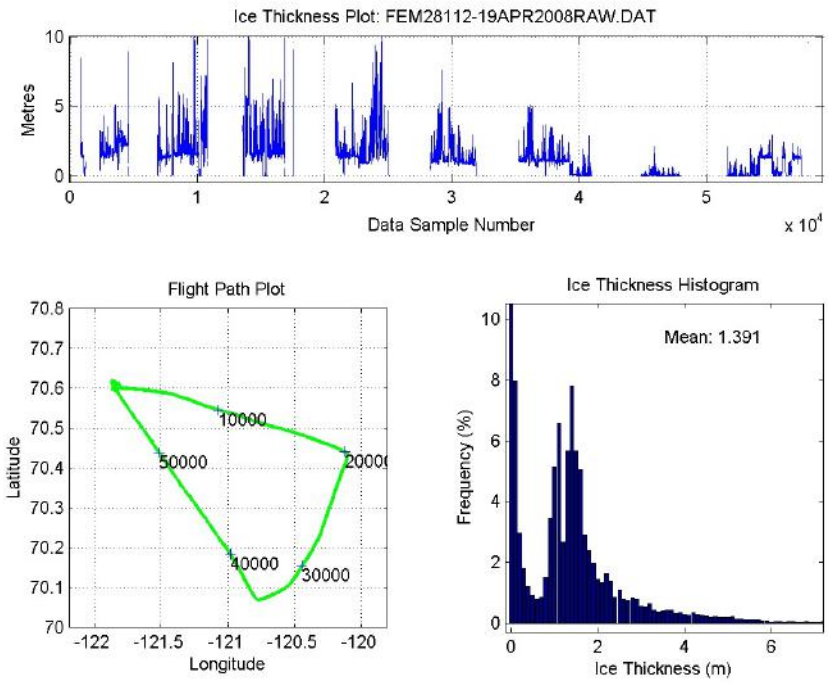

Figure above shows the thickness line plot along the 150km triangle flown morning of April 19 with the ship in the upper-left corner (70.6 N latitude) at about 5-6m above the ice. Video data was sampled at line sections at a height of 130m where no ice data was collected, At this height the video frame width is 150m wide.

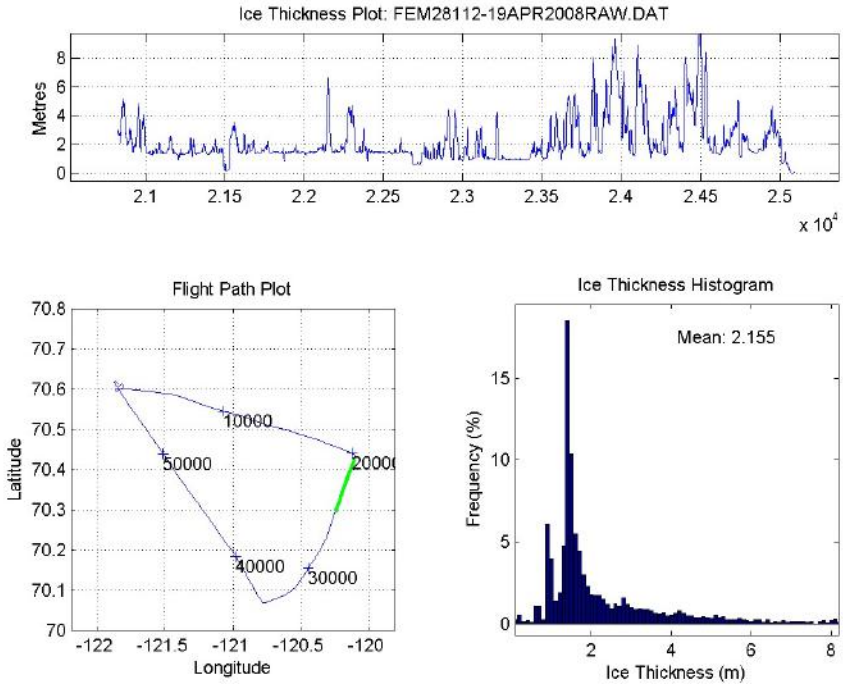

An 12km section of line track (112) shown in previous figure that shows ridges up to 8m, mean flat ice thickness of 1.4m, old lead (at 2.27) 63cm thick and thin ice section of 95cm (at 2.33).

The video frames were collected with an AXIS 210 Network Camera using an 4mm lens for 250 pixcels across the camera's frame width providing a resolution of 1/2m at the 130m flying height. It is housed in a "Pod" along with a laser (Optec Sentinel 3100 laser) that is strapped to the helicopter skid gear. The computer program reads the flying height and helicopter speed to collect camera frames

with an 50% overlap. This means every 60m along the track an frame is collected or 16/km (or 1000frames per triangle).

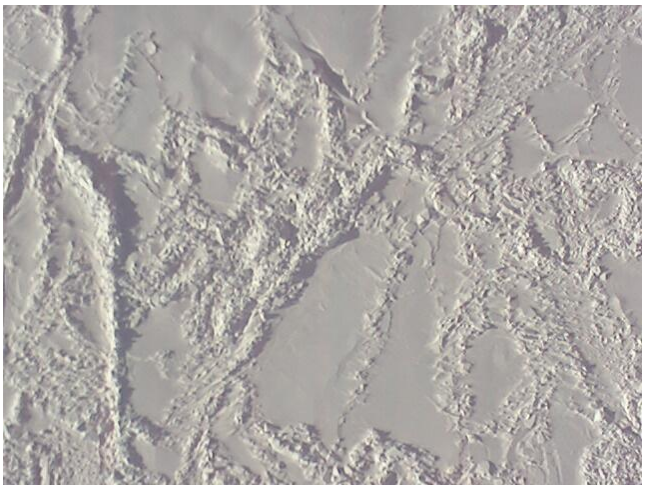

Figure above shows a video picture from the April morning flight 122 showing the rough rubble fields with ice thickness up to 8meters as shown in the line plots shown above. Frame width is approximately 1.2height of 400ft or 150m. The shadows created with the sun in the SE indicates that the helicopter was flying to the NW on its way back to the ship. Sun's shadows in the morning and evening provide additional 3-d information to the picture in addition to the orientation of the picture.

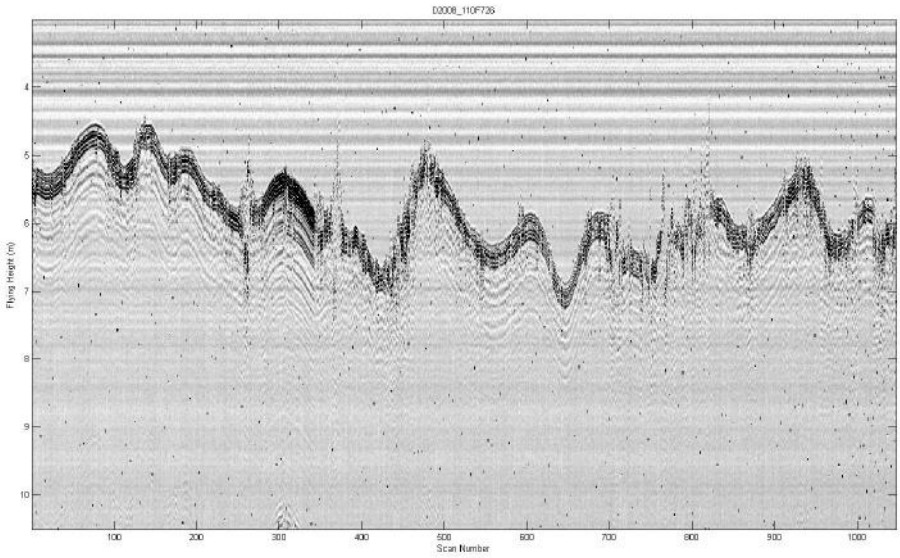
A ground-penetrating-radar (GPR) is used to determine if snow depths can be monitored. The GPR used is a Noggin-plus 1000 by Sensors & Software Inc. It has a frequency of 1000MKz and is used to measure freshwater ice thicknesses of ice roads behind truck. The GPR is housed in a second "pod" strapped to the helicopter skid gear. It operation functions along with those of the video camera are controlled through cables by a laptop inside the helicopter. The GPR as an helicopter-borne sensor has provided freshwater ice thicknesses for a test lake on Prince Edward island before being brought up here on the CFP-IPY program to evaluate if it can also measure thick snow depths.



Plot of GPR file 726 which at 10scans per sec and speed of 30m/sec means the total length of the record is 3km and covers an area of rough ice where snow dunes of 40cm can be found. Hard ego is from the ice surface and its oscillation shows the flying height variability of the helicopter 6-7m. It is assumed the greyer ego areas indicate snow areas and the hard ice ego is reduced due to energy absorption in the snow. This needs to be verified by a snow dune test.

Table of helicopter and sled EM data files

date	EM File	other sensors	survey/test	area	data length
April 8-9	*125-128*	sled	calibration	Thick –thin ice	500m
April 8-9	*127-130*	sled	ship floe 1	To/from thin ice	1000m
April 11	*131-134*	sled	ship floe 2	Old to new location	500m
April 12	*135-138*	sled	ship floe 2	Landing strip	2000m
April 12	*138-139*	sled	ship floe 2	to Andrea no snow	400m

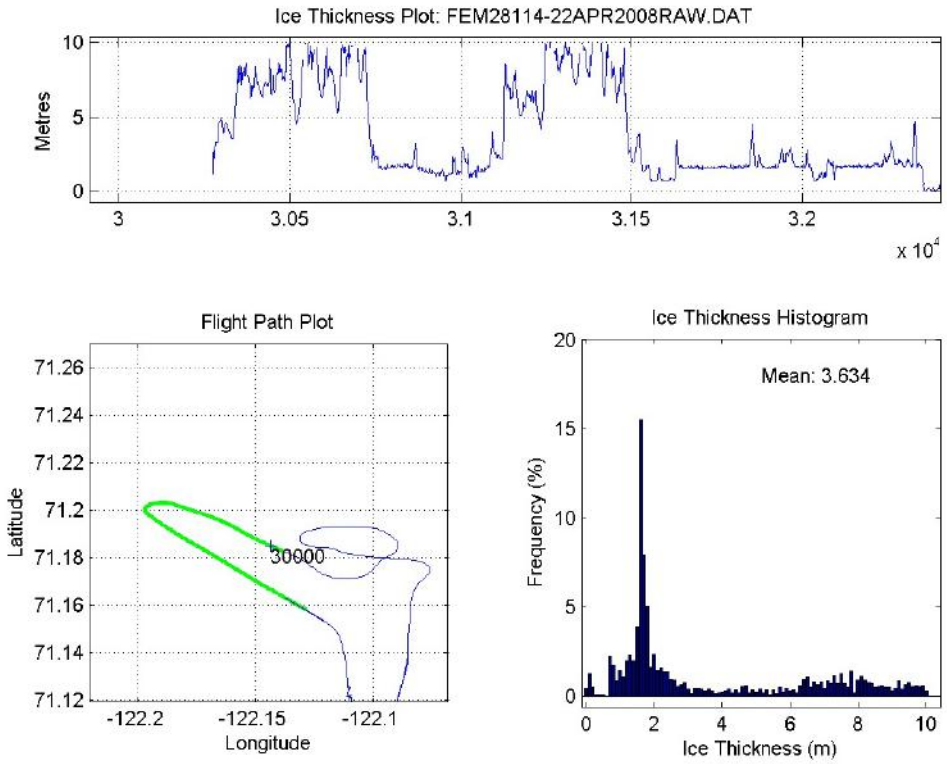
April 13	*143-145*	sled	ship floe 2	Cleared ice area	300m
April 16-21	*146-147*	sled	ship floe 3	EM cal. lines	400m
April 16	101-104	----------	EM test	ship	-------
April 17	108	----------	EM test	ship	-------
April 17	109	Video-GPR	Survey	SE flat triangle	90km
April 18	110	Video-GPR	Survey	W to NW triangle	145km
April 18	111	Video-GPR	Survey	N to NE triangle	140km
April 19	112	Video-GPR	Survey	W to SW triangle	140km
April 19	113	Video-GPR	Survey	E to SE triangle	150km
April 22	114	-------	Reco	North to Banks Isl.	-------
April 22	115	Video-GPR	Survey	Near the Ship	55km
April 23	116	Video-GPR	Survey	S to SE triangle	120km

On April 22, a reco flight to find a new runway just north of our site and to Banks Island to check on the old runway as another possible fall-back position. Below is a picture of the old flaw lead of 60cm ridge to up to 10m , or reduced to 1/15 of its width. The ridged area near the old runway was passed over twice, the inshore land-fast ice against it crunched it 1.7m to 1.0m thick (sample section 3.1. there is still a small area left of the old flaw lead (sample section 3.16 now showing a thickness of 73cm, the thick floe the ship was anchored can be seen between 3.16 to 3.24 and was at this location 1.6m thick.



Tuesday and Wednesday April 22-23, 2008 -survey
A small survey was done on April 22 (115) around the ship while others removed the equipment from the ice; total track flight length of 55km. On Wednesday afternoon a triangle was flown to the SE and E PIC file 114. Most of the ice seen there was very thin mostly old frost flower ice covered with snow 15-20cm. Three GPR passes were done over the measured snow line before returning to the ship

Summary CFL-EM survey

- Ice thickness and roughness data set were collected over the middle of the Amunsden Gulf during April 17-23, 2008 with helicopter-born sensors. An estimated profile length of over 400km was collected in 5minute subsections by the EM-Laser system from 5-7 altitude along with 400km flight subsections of video data from 120m altitude.
- Ice thickness profiles were successfully collected with an EM sled while the ship was stationed in the pack ice. Total linear length covered by foot pulling the sled is approximately 5.5km mostly done prior to April 16.
- Ground-Penetrating-Radar data was collected during ¼ of the EM flights to estimate snow depths. Only data was collected over thick ice where visually deep snow areas were seen. Video and GPR data to April 22 archived on two CDs.

2.3. Team 3

2.3.1. Primary Production

PI: Michel Gosselin

Introduction
Primary producers fuel nearly all of the Earth's ecosystems by converting the sun's energy to an available food source through a process called photosynthesis. During photosynthesis, primary producers fix carbon dioxide, an important greenhouse gas, into food molecules connecting them, albeit indirectly, to our global climate. In this project we have focused our efforts to better understand physical (e.g., light) and chemical (e.g., nutrients) factors affecting primary production within the circumpolar flaw lead within the Amundsen Gulf.

In seasonally ice-covered seas, primary producers can be found in two generalized environments (habitats): (1) associated with sea ice (ice algae) and (2) suspended in the upper water column (phytoplankton). The timing, intensity and duration of primary production in these two environments are different. Both habitats play a very important and integrated role within the ecosystem. In a typical Arctic marine ecosystem, the relative importance of sea ice algae and phytoplankton follow a seasonal progression, with sea ice algae providing an initial food source for heterotrophs in early spring when the region is ice-covered, followed by a shift to phytoplankton production as the ice melts away during summer months. However, in the flaw lead system where open water can exist even in winter, the general location of primary producers is understandably much more complex. Contrasting the environments of primary producers in the flaw lead with the surrounding ice cover is a driving goal of our research. Furthermore, we have not had the opportunity to examine this dynamic region throughout the entire year, until now with the Circumpolar Flaw Lead System Study.

The Sea Ice Community
A very unique community exists within the inter-connected brine channels and brine pockets found between the larger ice crystals of the sea ice matrix. Therefore, within the sea ice, our group has focused not only on the primary producers, but on the entire community from bacteria through to

meiofauna. In this section we describe the sea ice community dataset collected during leg 7 of CFL (March 14 – April 24, 2008).

Ice samples were mainly obtained via ice core extraction using 9 cm core barrels (Kovacs© Mark II Coring System). Ice core sampling was conducted every 3 days or on the first sampling day after arriving at a new ice floe. Depending upon the analysis needed and the snow depth available, cores were collected under low (< 5 cm), medium (8 – 15 cm) and high (> 15 cm) snow covers. General measurements taken at each core hole included snow depth, ice thickness and freeboard. Our group also worked closely in the field with teams 2, 6 and 7 to collect data on PAR albedo, transmitted PAR, vertical profiles of temperature, salinity and concentrations of various gases in the sea ice (e.g., CO_2, CO, N_2O and DMSP) and nutrients of the sea ice. Another method to obtain material from the ice involved collection of samples by SCUBA divers. The following sections are separated into sea ice algae and sea ice meiofauna.

Sea Ice Algae

State Variables

If available, 3 snow depths were targeted at every sampling station. The bottom 0 – 3 cm and 3 – 10 cm sections of the ice cores were collected from each snow depth. Depending on the amount of material needed for analysis and the amount of algae visible in the sea ice, 4 to 7 cores were collected from each snow depth site. One of the medium site ice cores extracted was also used for a full vertical profile. Ice cores were pooled in cooler jugs and 0.2 µm filtered seawater (FSW) was added at a dilution of 100 ml FSW per 1 cm of core prior to melting. The samples were then left to melt overnight in the cooler jugs. Once melted, nutrient (Nut) samples were taken, followed by a measurement of the salinity and total volume of the samples. It is noted that nutrient samples for FSW were collected as well as nutrient samples for additional core sections (i.e., no FSW added) which were stored in whirl-pack bags and placed in darkness to melt.

The dive program also allowed for collection of bottom ice samples via slurp guns (Fig. 3.1). This method of sample collection is quantitative and minimizes stresses such as osmotic shock on organisms during collection. Slurp gun samples were analysed identically to ice core extraction samples, except the addition of FSW was not required.

Samples were filtered for determination of size fractionated chlorophyll *a* (chl *a*), particulate organic carbon and nitrogen (POC/N), spectral absorption of particulate matter (Ap), high performance liquid chromatography pigment analysis (HPLC), general cell identification (Cells; fixed in Lugol Acid and Formalin and to be counted via inverted microscopy), cell identification of autotrophs and heterotrophs via epifluorescence microscopy (Epi), abundance and size class of pico/nanoalgae and bacteria via flow cytometry (Cyto) and DNA fingerprinting of ice samples (DNA) (Table 3.1). Table 3.2 lists the same analysis, except for slurp gun samples. Furthermore, at every medium snow depth site listed in Table 3.1, a vertical profile core was collected for determination of Chl *a*, Cells, Ap and HPLC.

Figure 3.1. Image of one of the SCUBA divers collecting a bottom ice slurp gun sample.

Table 3.1. Data collection timeline for ice core extraction samples. L, M and H stand for low, medium and high snow depths and thin represents ice less than 70 cm thick with a 3 – 4 cm snow cover.

Rate Variables

During leg 7, samples were collected to measure carbon uptake by algae under varying light conditions via ^{14}C labeling. Increasing light intensity is plotted against carbon uptake per unit chl *a* to create Photosynthesis-Irradiance (PI) curves. These curves are used to determine parameters such as the algal photoacclimation and maximum carbon uptake per chl *a* biomass. Two separate methods were used to collect the samples. The first method involved scraping the bottom of an extracted ice

core into a known volume of FSW in the field. This method minimizes osmotic stress on the algae. The second method was to collect samples via the slurp gun (Fig. 3.1).

The samples were also analyzed using two separate methods. The first method was an under ice incubation array deployed by either an under ice arm or by divers (Fig. 3.2). Samples were placed into 60 ml culture flasks and covered with a range of neutral density filters used to block a known percentage of light per flask. A Licor© PAR sensor was positioned in the center of the incubation array to log incoming light during the incubation. When deployed by divers, the under ice surface was scraped to remove existing algae and the incubation array was placed under the scraped portion of ice. The second technique was a small volume, short time incubation method as described by Lewis and Smith (1983). The incubation set-up, referred to as a photosynthetron, was connected to a cooling bath and incubations were run at -1.5 °C. Light intensity experienced by the individual vials during an incubation run was measured using a Biospherical Instruments QSL-100 scalar PAR sensor.

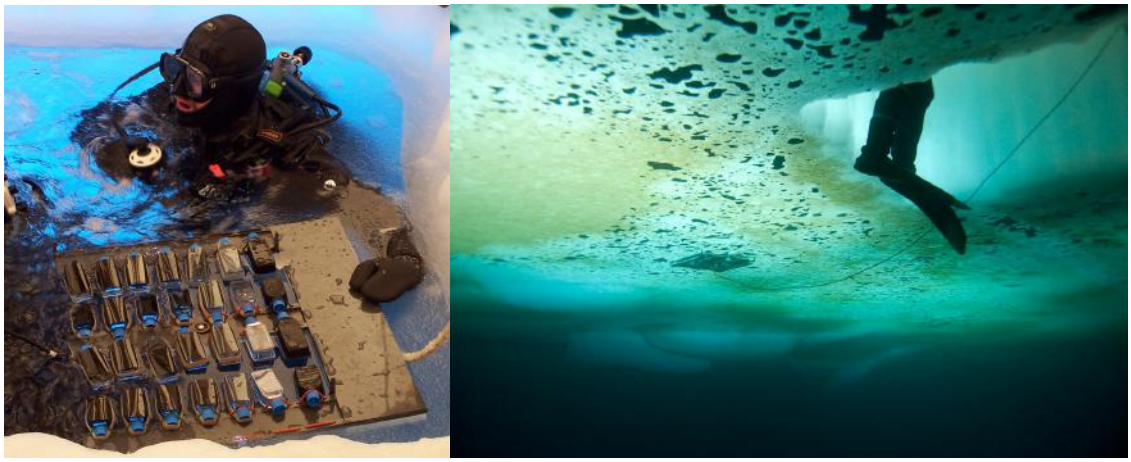

Figure 3.2. Image of the under ice incubation array (left) and the array deployed under the ice attached to a PAR sensor cable leading to the surface through the dive hole (right).

Table 3.3. Data collection timeline for PI curves. L, M and H stand for low, medium and high snow depths and thin represents ice less than 70 cm thick. Slurp and scrape represent samples collected by a slurp gun and bottom ice scraping of extracted core samples into FSW, respectively.

Fatty acids and Particulate Phosphorus

Stig Falk-Petersen, Anette Wold
Norwegian Polar Institute
stig.falk-petersen@npolar.no
anette.wold@npolar.no

Our group has collaborated closely with teams 3 and 4. The aim of our work is to study the effect of light on the food quality of ice algae and the transfer of energy from algae via *Calanus* copepods and ice amphipods in Arctic ecosystems in ice covered waters. We will use this to compare and contrast key ecosystem component between the Canadian Arctic and Svalbard waters, Norway. The samples

collected during Leg 7 will be used by Post doc Eva Leu (ice algae), Post doc Janne Soereide (zooplankton) and PhD student Henrik Nygaard (Ice amphipods). Sampling of ice amphipods will be continued by Haaakon Hop on Leg 9a.

The aim of the ice algae sampling is to study the effect of light on nutritional quality of ice algaes in terms of fatty acids and elemental stoichiometry. Samples were taken from different types of ice floes, different snow depths (high and low) one - two times a week. In total we sampled 7 times during the 5 weeks (Table 1). Three ice cores were collected at each site (high and low snow cover). The bottom 3 or 5 cm of the cores (depending on the amount of ice algae) were cut off and kept in the dark. The cores were melted in filtered sea water; 100ml sea water was added per 1 cm core. At station D36, D38 and D41 samples were also collected from the interface between the ice and the sea water. These samples were collected by the divers using a slurp gun. The samples were filtered on pre-burned (450°C) GF/F 25 mm filters and frozen at -80°C. The samples will be analyzed for fatty acid composition and particulate phosphorus. Three pseudo-replicates were taken for each parameter for each core, if there was enough material. All sampling were done at the same time and location as the other ice core sampling.

Table 3.4. Ice algae samples for fatty acid and particulate phosphorus.

Ice Algae Biomarkers

Thomas Brown
University of Plymouth
thomas.brown@plymouth.ac.uk

Objective:
An investigation into the use of compound specific biomarkers from sea ice diatoms to determine the presence of past Arctic sea ice.

Background:
Previously, the Plymouth team (Guillaume Masse, Simon Belt, Lindsay Vare and Thomas Brown) have demonstrated that an unusual chemical biomarker, derived from sea ice diatoms, can be detected in sediments below sea ice, thus providing a proxy measure for sea ice cover in the past. Analysis of sediment material collected with the help of Dr. A Rochon (UQAR) and his colleagues during the 2005 ArcticNet cruise revealed the presence of this biomarker across the entire Canadian Arctic Archipelago from the NOW region through to the Beaufort Sea. Notably, analysis of extracted sediments showed significant temporal and spatial variations in the concentration of the sea ice biomarker, indicating variations in sea ice cover in the past and between different locations. The aim of the current fieldwork was to obtain a series of sea ice cores encompassing various physical, temporal and spatial variations in order to investigate factors effecting biomarker concentration. These data would then be calibrated against satellite records of sea ice over the region.

A further aim of the current fieldwork was to collect sufficient amounts of representative species of the Arctic ecosystem in order to be able to perform analyses of their lipid contents and study the transfer of sea ice biomarkers across food chains. planktonic specimens were to be collected using nets. Box core sediments were also obtained from stations relating to ice covered regions.

Sampling:
Box core sediments were collected from a range of locations in the Amundsen gulf. Sampling consisted of bulk homogenised surface sediment. Stations sampled were D34, D35, D37 and D39.

Plankton net tows were collected at every opportunity throughout the cruise and samples from both vertical tows (50m water column – 50um) and horizontal tows (~100m tow – 50um) were pooled separately and frozen (-20^{o}C) for later analysis of biomarker content in the UK.

Sea ice cores were collected regularly in an attempt to capture the spring sea ice algal bloom. Cores were sampled in triplicate to determine local variability in algal and biomarker production as well as from areas of low snow (~2cm) and high snow (~30cm) to determine irradiance effects. Opportunistic cores were also sampled in interesting features such as pressure ridges, frozen cracks, lead edges, new ice (~10cm) and thin ice (~50 - 70cm). Cores were melted (bottom 10cm) and filtered (0.7 GF/F). Samples were frozen (-20^{o}C) and taken back to the UK for analysis. Selected triplicate cores were sectioned at 1cm over the bottom 10cm and filtered. Thin section cores will be used for isotope analysis. Stations sampled were D29, D31, D32, D33, D36, D38 and D40.

Dive samples were obtained from the onboard dive team. A scraping device was manufactured on board to remove and collect the bottom 2~3 cm. Slurp guns were also used to sample the under ice community. Samples were filtered (0.7 GF/F) and frozen (-20^{o}C).

Our analysis, briefly, consists of solvent extraction, open column chromatography and Gas Chromatography - Mass Spectrometry.

Meiofauna

Chantal Lacoste and Maike Kramer

Program of Chantal Lacoste
Institut des Sciences de la Mer (ISMER)
Université du Québec à Rimouski (UQAR)
chantal_lacoste@yahoo.com

Ice samples were taken for studies on diversity, abundance and feeding ecology of sympagic meiofauna (metazoans between 40 µm and 500 µm living within the ice). Most dsamples were collected by extracting ice cores. Every three days, three ice-core bottom sections (3 cm length) were taken on a site of non-deformed ice with low snow cover (< 5 cm), and three with high snow cover (> 20 cm) for analyses of meiofauna diversity, abundance and biomass. Also every six days 3 additional ice-core bottom sections (3 cm length) were taken from each site for stable isotopes analyses on animals and particulate organic matter (POM). Additional samples were taken by SCUBA divers using the slurp gun and ice scraper (20 µm mesh) for sub/bottom ice samples.

Bottom sections of ice-cores were melted in 500 ml of FSW (0.2 µm) in the dark at 4 °C. Samples obtained from the scraper were also melted in FSW however slurp gun samples did not require addition of FSW. Once melted, 4 ml of the samples were pre-filtered on a 40 µm nylon mesh and placed in a 5 ml cryovial stored at -80 °C for bacterial counts via flow cytometry. The volume of the remaining melted samples was measured and then sieved on a column of 500 µm followed by a 40 µm mesh. The material obtained from the 40 µm sieve was fixed with NBF formaldehyde 4% in 20 ml plastic vials and stored at room temperature for future counting. The six extra cores obtained for stable isotopes analyses and part of the samples obtained from the SCUBA divers (scraper and slurp) were sieved as previously described. The animals obtained on the 40 µm sieve were separated per group, counted and rinsed with milli-Q water on a Whatman GF/F fiberglass filter and stored in petri dishes at -80 °C. The water obtained from the sieving was then filtered on a Whatman GF/F fiberglass filter and stored in petri dishes at -80 °C.

Ice samples were taken for studies on diversity, abundance and feeding ecology of sympagic meiofauna (metazoans > 20 µm living within the ice). Every three days, five ice-core bottom sections (5 cm length) were taken on a site of non-deformed ice with medium snow cover (4-18 cm), nearby the PAR measurement area, for measurement of algal pigments (bottom section 1) and for analyses of meiofauna diversity, abundance and biomass on fixed (bottom section 2) and fresh samples (bottom sections 3-5). Once per floe, one full ice core, cut in sections of 2-10 cm, was taken instead of bottom section 2 for analyses of meiofauna abundance and biomass on fixed samples with respect for vertical distribution. On the same sampling day, further three ice-core bottom sections (3-5 cm length; bottom sections 6-8) for analyses of meiofauna *in situ* gut contents were taken at sites with high, medium and low snow cover. Further ice samples, including ice-core bottom sections (3-10 cm length), ice underside (2-5 cm thick layer) scraped from blocks of ice and pieces of ice picked up from the water next to the ship using the ice cage, were taken in order to gain meiofauna organisms and sympagic ciliates for fatty acid analyses and feeding experiments.

Bottom section 1 was melted in the dark at 4 °C and filtred on a Whatman GF/F glasfibre filtre; algal pigments were extracted in acetone in the dark at 4 °C, and chlorophyll a and phaeopigment a were measured fluorometrically. Bottom sections 6-8 were immediately placed in 50 ml of 0.2 µm filtred sea water (FSW) and shaken gently for one minute to flush out meiofauna organisms. The liquid was sieved on a 20 µm gauze, and the samples were fixed in picric acid formaldehyde (PAF) and stored at 4 °C. In the home laboratory, meiofauna will be sorted from these samples and cut in half, and the gut content will be analysed using a scanning electron microscope. All other ice samples, as well as the remains of bottom sections 6-8, were melted in an excess of FSW (200 ml per 1 cm of ice core) at 4 °C and sieved on a 20 µm gauze. Bottom section 2 / sections from the full ice core were then fixed in borax-buffered formaldehyde (37 % formaldehyde added to the sample, final concentration 2 %). Bottom sections 3-5 were sorted onboard at 4 °C within two days after melting, and bulk abundances of meiofauna and ciliates were determined. All other ice samples were sorted onboard at 4 °C within a few days after melting.

Part of the organisms sorted from the samples onboard were preserved in formaldehyde (2-4 %) or PAF for later taxonomical and morphological studies. For fatty acid analyses, alive animals were rinsed by transferring them into fresh FSW several times, were then transferred onto a pre-combusted Whatman GF/F filtre, rinsed with MilliQ water, and stored at -80 °C. In the home laboratory, the samples will be extracted in dichloromethane:methanole (2:1 v:v), transesterificated and analysed in a gas chromatograph. The fatty acid composition will provide information on in *situ diets* (e.g. the degree of carnivory). For feeding experiments during Leg 8 and in our home laboratory, cultures of sympagic meiofauna have been established.

Remote Sensing

Pierre Larouche
Institut Maurice-Lamontagne
Pierre.Larouche@dfo-mpo.gc.ca

Introduction

To understand and to monitor biophysical processes in complex coastal waters it is necessary to use remote sensing methods. CASES measurements showed that optical properties of the Beaufort Sea and

the Amundsen Gulf region are dominated by the freshwater outflow from the Mackenzie river leading to a bias in the estimation of phytoplankton biomass using remote sensing data. There is thus a need to develop specific methods to make more effective use of remote sensing data. The building of a database of inherent optical properties relating a wide variety of physical and biological conditions is a crucial step towards this goal.

The general objective of our team is to study the relationship between the spatial and temporal distribution of the phytoplankton and the physical environment in the canadian Arctic with an emphasis on the Beaufort Sea and the Baffin Sea using remote sensing data.

Specific objectives for the CFL 2007-08 cruise are:
The estimation of the ability of current bio-optical algorithms to measure chlorophyll-a concentration and species discrimination;
The development of specific algorithms for a variety of ocean color sensors which will in turn provide a better understanding of the Beaufort Sea and the Baffin Sea physical and biological processes;
The analysis of light absorption properties of arctic phytoplankton.

To reach these objectives, we will measure throughout the program the following parameters whenever possible:
the transparency of the water with a Secchi disk;
vertical profiles of inherent optical properties (light absorption and transmission, backscatter light, volume scattering function, particle size spectra, phytoplancton fluorescence, CDOM fluorescence, temperature ans salinity using a custom built optical profiler system;
the pigment composition of phytoplankton with the high performance liquid chromatography method (HPLC);
the algal pigments light absorption;
the total suspended matter and its partition into organic and inorganic matter;
the chromophoric dissolved organic matter concentration.

Methods
Water samples were taken from March 24 until April 5 under the thinner ice of a refreezing flaw lead close to the southeast coast of Banks Island at station D33. Another time series was made at station D41 at the edge of the floe where the ship was parked using the skippy boat. Samples were taken using a pump and a hose lowered through a small hole perforated in the thin ice with a handheld ice auger. Samples were taken at depths of two and five meters from the surface water level. Ice thickness during the experiment slowly increased from 50 to 65 cm. Two other samples were also taken using the rosette system at depths of 10 and 25 metres. Measurements were also made at other locations throughout the area while the ship was moving.
Filtrations were performed for chlorophyll determination (HPLC techniques), a_{ph}, total suspended matter (TSM) and chromophoric dissolved organic materiel (CDOM). For chlorophyll-a, and algal pigments, water samples (up to 2.5 litres) were filtered through 25 mm GF/F filters, flash freezed and stored in liquid nitrogen on the ship. Samples will be transported south for analysis at the end of the leg. CDOM samples were filtered using 0.2 µm Anotop® syringe filters (Whatman) and collected into 60 ml acid-cleaned amber glass bottles. The bottles were stored frozen (-20 ˚C) in the dark on the ship. Samples will be transported south for analysis at the end of the leg. Total suspended matter was measured by filtering up to 2 litres of water using pre-weighted 25 mm GF/F filters. The filters were stored on the ship at –80 ˚C, to arrest pigment degradation (Sosik, 1999), and will be transported south at the end of the leg to complete the analysis. Some vertical profiles of inherent optical properties were made from April 5 to April 22 from the moonpool. However, a defective AC9 greatly limited the use of the profiler. Detailed sampling activities up to April 22 are summarized in Appendix.

Conclusions
The CFL LEG7 operations were successfully completed between March 13 and April 24. This was a good leg that allowed to measure optical properties before the phytoplankton bloom started. The chiefs

scientists were comprehensive of the particular needs of the optics team. We are particularly indebted to the crew members and Schools on Board students who helped with some operations.

The upper water column underneath the sea ice was sampled regularly with the ice core collection. Samples at the ice-water interface (sfc) and at 2 and 5 m depths were obtained via a small battery powered PVC pump (Cyclone Products ©) equipped with a 450 µm nitex mesh. The sfc sample was collected with the assistance of an under ice arm. Depths at 10 m or greater were collected by the rosette through the moonpool. The samples collected and the analysis to be accomplished on these samples are provided in table 3.X.

Table 3.8. Water samples collected during regular ice coring stations.

2.4. Team 4

2.4.1. Zooplankton and fish Acoustic

PI: Louis Fortier
Participants: Gérald Darnis (U. Laval), Catherine Lalande (U. Laval), Luc Michaud (U. Laval), Brigitte Robineau (U. Laval), and Pascal Massot (electronic technician from U Laval), with the contribution of Stig Falk-Petersen and Anette Wold from the Norwegian Polar Institute.
Written by: Gérald Darnis, Brigitte Robineau, Anette Wold, Stig Falk-Petersen, Catherine Lalande, and Luc Michaud

Introduction
The fragmented, thin, and often absent ice cover in the flaw lead allows solar radiation to reach the surface layer of the ocean where it triggers photosynthesis by microscopic algae. Team 4, Pelagic and Benthic Food Web, will investigate how and to what extent the microalgae growing in the flaw lead are exploited by animals living in the plankton (the zooplankton) and on the sea floor (the benthos). Our simple hypothesis is that, relative to adjacent ice-covered regions, enhanced algal production in the flaw lead translates into biological hot spots where higher zooplankton and benthos abundances prevail. We will also investigate how the Arctic cod, a central species in the Arctic food web, uses the flaw lead for feeding, overwintering, reproduction, and as a nursery ground for their young stages (http://www.ipy-cfl.ca/page1/page1.html).

General objectives
The objectives of the team on leg 7 were in part to continue the work made during the previous legs and also to install the under ice towing system that permits to sample efficiently the surface layer and under ice habitat for Arctic cod larvae. Our sampling program was designed in the continuity of the overarching goal of ArcticNet project 1.4 led by Dr. J.-É. Tremblay (U. Laval) 'Marine productivity and sustained exploitation of emerging fisheries' which is to assess the impact of sea-ice cover reduction and increasing sea temperatures on biological productivity, fisheries resources and marine mammal populations of the coastal Canadian Arctic. Since October 18th, date the CFL program started, we focus on how the physical processes moderate biogeochemical processes within the changing northern flaw lead ecosystem nearby Banks Island (Beaufort Sea). Our multidisciplinary ArcticNet-CFL team is strongly linked with Team 7 (Carbon Fluxes – Tremblay) of the CFL program. For this leg-7 of CFL, sampling efforts were concentrated on the pelagic secondary producers.

The primary objectives of our team during CFL-7 were:
1- To assess zooplankton / fish abundance and diversity by using various plankton nets.
2- To track zooplankton / fish biomass and distribution with the EK60 Echo sounder.

Our secondary field objectives were to collect and use the zooplankton sample for:

- The cycling of contaminants in zooplankton (G. Stern, U. Manitoba)
- Identification of the sources and pathways of omega-3 in the arctic marine food chain (J. Michaud, E. Dewaily and L. Fortier, U. Laval). This project linked to the CFL-URSUK program and the ArcticNet theme 1.5, focusing on the importance of omega-3 fatty acid in the traditional diet of Inuit communities.
- Assessment of the biomass and respiration rates of the zooplankton community by the Electron Transfer System (ETS) activity at chosen stations (G. Darnis and L. Fortier).
- Stable isotope analysis on the food web structure and carbon fluxes; this is a joint project between Team 4 and 7 of CFL (A. Forest, L. Fortier, J-E. Tremblay)
- Copepod *in-situ* egg production (EPr) and gonad maturation of *Calanus* glacialis, *C. hyperboreus* and *Metridia longa* (M. Ringuette, G. Darnis, L. Fortier).

A team from the Norwegian Polar Institute joined the team 4 on this leg and participated actively to the sampling. They have a project of their own that is in part related to the study of the energy transfer from algae to *Calanus glacialis*. The section of their report that focuses on zooplankton work is incorporated at the end of the present report.

Sampling program

The first part of Leg-7 sampling program was oriented towards ice work, when the ship was stationary on an ice floe for periods of time varying from 1 day to a week. On the second week of the leg, the decision was made to the installation of the under ice towing system. We started to look for a flat surface of ice free of cracks and large enough to bear a hauling system with its two ice holes 1000 m apart. Unfortunately no such floe was available in the vicinity of the ship and we had to reduce our ambition to a 450 m long installation at station 2008D33. It took the team four days of strenuous effort to achieve this work. Without the precious help of the ship's crew this would have most probably not been possible. The system was used on three occasions for oblique and under ice sampling (Table 5). The capture of our first arctic cod larva was promising. However right after the mid-leg crew change, unfavourable winds suddenly pushed the ship in the direction of the Bank's Island. The threat of having the ship crushed between the coast and thick and solid ice pushed for the decision to abandon the site. We hastily removed the rope under the ice and the frames covering the ice holes before fleeing toward better ice conditions. This event was a serious drawback to our cod sampling program. We never found again the opportunity to install another system during the remainder of the leg, which we could bequeath to the next zooplankton team. As an alternative we tried to haul the ring net in leads completely free of ice, using the Skippy boat. This proved to work well but these leads were elusive and the Skippy boat was heavily used for the needs of other teams. As a consequence, this experience occurred only once during our painful wanderings in heavy ice in search of ice floes large enough to be used for all the teams involved in sampling on the ice. Vertical sampling of the water column from the ice, initiated during the previous legs, was continued as well as the usual moon pool zooplankton sampling activities. However a reduced team and the many times the ship got stuck during our displacements had the effect to decrease the sampling frequency of this leg compared to the two previous ones.

1) Sampling gear and events

a) 1-m^2 Square net. Frame rigged with a 1 m^2 mouth opening net (1 x 200, µm mesh), out-rigged with a 10 cm diameter net (50 µm) and equipped with a TSK flowmeter (Figure 1a). This net is used for integrated water column sampling that is summarized in table 1. When deploying, downward winch speed was <40 m/min to avoid mixing of the nets, and upward winch speed was 30m/min. To obtain quantitative tow (i.e. for taxonomy and abundance estimates), the content of the 200 µm (TSK) and the 50 µm mesh-net were preserved in formaldehyde (Fortier). Qualitative tows (i.e. 'live tows') were also performed to obtain animals for contaminants, lipids, EPr and/or ETS studies.

b) Hydrobios. Multi-depth plankton sampler (Figure 2b) equipped with nine 200 µm-mesh nets (opening 0.5 m^2). This was allowing for depth specific sampling of the water column. The *Hydrobios* is also equipped with a CTD to record water column properties while collecting biological samples. When deploying, downward winch speeds was 40m/min and the speed up was 30m/min. At most casts, the net collection was preserved in formaldehyde for taxonomic analysis but for some casts, the content of each net was divided: 50% for taxonomy (4% buffered formaldehyde) 25% for biomass estimates and 25% for ETS analysis (Table 2). The Hydrobios flowmeters appeared again to be functioning perfectly after the troubles of leg 3 and 4. A 24-hour Hydrobios sampling involving 4-hour intervals deployments was made during the leg. The targeted date for this sampling event was close to mid-leg but continual repositioning of the ship due to heavy drifting postponed this to the end of the second last week of the leg.

c) Ring net. A 1m diameter ring net equipped with a 200 µm mesh net and out-rigged with 10 cm diameter net (50 µm) and a GO flowmeter. This net was deployed at least three times per cast from a hole in the ice at proximity of the ship but at a site not influenced by its presence. On a few occasions

the net was deployed from the ice edge of the floes sampled (Figure 2c). Ice zooplankton sampling activities are summarized in table 3. A RBR CTD was added to the net frame. At each station cast, the first haul was from 10 m to the surface and the second haul from a maximum of 270 m to the surface. A third haul from 60 m to surface was carried out to augment the sampling effort to collect Arctic cod larvae and juveniles. The net was lowered manually to the desired depth and pulled manually for the 10 m haul and using a motorised engine for the deeper hauls during the first cast. One visited ice floe was too small and unstable to bear motorised vehicles and thus the nets had to be pulled by hands. The consequence was that the deep hauls were cancelled at that site. Sampling from the ice edge proved difficult at times when thin ice was pushed by the current against thicker ice, forming ridges that prevent normal sampling. Again, the deep net tow was cancelled under these conditions.

d) Double net
Frame rigged with two 1 m^2 mouth opening net (2 x 500 µm mesh), out-rigged with a 10 cm diameter net (64 µm) and equipped with a GO flowmeter (Figure 2d). The gear is deployed from one hole of the hauling system on the ice and towed to the other hole by the half track (BR). Added to the operator of the BR, people at both ends of the system are required to verify that the rope is unwinding correctly through the pulleys. Two floats are fixed on the frame for under ice casts and removed for oblique hauls from one ice hole to the other.

e) Gill net
A 40 m long net deployed vertically from the bottom to 40 m above (Figure 2e). One of the ice holes was used for 24h00 deployments. This sampling is used to collect adult fish.

f) Rosette
Nine depths are sampled for water using the bottles of the rosette in the moonpool. Two bottles per depth are taken and their content sieved through a 50 µm sieve. The particles retained are preserved in formaldehyde. This method is used to study the vertical distribution of the zooplankton size fraction under 200 µm that is not retained by the nets of the Hydrobios.

Overall, 122 sampling events occurred and 77 of the samples obtained were preserved for taxonomy, and the remainder, the 'live tows', were used for further analysis and laboratory experiments as described above. Samples for lipid and stable isotope analysis were placed in cryovials and stored at -80˚C. During the course of the leg, requests were made for samples preserved as a bulk at -80˚C for later gut fluorescence measurements. These samples will be sorted and analysed at Laval University. Samples of ice algae were also collected upon request for lipid analysis. Samples for contaminants were sorted and preserved by Gary Stern's team. On a few occasions, usually corresponding to box core deployments, Dieter Piepenburg requested splits of zooplankton to verify the emergence of meroplankton larvae (Table 1).

Laboratory analysis

1) Egg production rate experiments
Copepod *in-situ* egg production and gonad maturation (after Niehoff 1998) were monitored by incubating large calanoid species females at 0°C, thus at a similar temperature that they experience at depth. *Calanus glacialis*, *C. hyperboreus* and *Metridia longa* egg production was assessed approximately every 5 or 6 days.

At the start of April, egg production rate of *C. hyperboreus* was still high (60 eggs fem^{-1} day^{-1}) but decreased drastically (6 eggs fem^{-1} day^{-1}). At the end of the leg, most of the females *C. hyperboreus* were spent, indicating the end of their reproduction season. Eggs were sampled for dry weight measurements. Approximately 200 eggs were put to dry on a pre weighed GF/F filter that will be weighed again on a microbalance at Laval University. Harsh winter conditions always provide difficulties in studying winter Arctic organisms. Because of this constraint, the metrics on the reproduction of *C. hyperboreus* is currently poorly documented. In order to measure the total production of *C. hyperboreus,* 50 immature females have been placed in filtered sea water during leg 5 and their egg production monitored daily. Eggs produced were then used to measure the hatching rates for different eggs buoyancies (sinking vs. floating). By the end of April we hope to get total reproductive output and the fate of this production. To this date, 20 females have spawned more than 1000 eggs. The record is presently held by female number 47 with a total of 1949 eggs spawned. However most of the females are spent and their lipid reserves are for many of them completely consumed. The egg production rate decreased greatly compared to the measurement of leg 6.

A large proportion of the females *Metridia longa* were in a mature stage of gonad maturation. Spawning was recorded on three experiments out of six but the rate of production remains low (1.66-6.3 eggs fem^{-1} day^{-1}).

The experiment initiated on leg 5 to test the hypothesis arguing that *Metridia longa* can feed on *C. hyperboreus* eggs. (Conover & Huntley 1991) was finally terminated. There was a high rate of mortality among the females after a few days even when they were fed eggs of *C. hyperboreus*.

An experiment carried out on females *Calanus glacialis* collected in the 60-0 m layer gave a fairly high egg production (25 eggs fem^{-1} day^{-1}) for the population of this species occupying the surface layer. Furthermore their guts were green with chlorophyll, most probably ice algae. We found no sign of egg production in other experiments for which females collected over the entire water column were incubated.

2) Biomass and Transfer System (ETS) activity
On five occasions, corresponding to five stations (Table 1 and 2), samples were sorted for biomass and ETS activity essay. At these stations, each Hydrobios net was subdivided: 50% for taxonomy (i.e. preserved in formol), 25% for population biomass estimates and 25% for ETS activity. For biomass estimate, the sub-sample (i.e. 25% of total sample) was fractionated with sieves in > 1000 □m and < 1000 □m size classes; these fractions were preserved at -20˚C. Sub-samples for zooplankton population ETS activity essays (i.e. 25% of total sample) were also sieved into the same two size fractions. As no Sanyo incubator was available for the ETS experiments, samples were incubated in a Pyrex plate filled with water and heated to 40˚C on a hot plate. Temperature of this 'hot tub' proved to remain constant during the required incubation time. ETS experiments were also performed on individual copepods, females and copepodite stage 5, of *Calanus glacialis*, *C. hyperboreus* and *Metridia longa.*

3) Respiration experiments
To derive respiration from the activity of the Electron transfer system a ratio of respiration on ETS activity is required. Thus incubations were carried out to measure oxygen consumption of copepods in sealed chambers. The handheld oxygen meter that we started to use on leg 6 proved to be very easy and practical to use for the respiration measurements.

4) Taxonomic analysis of the zooplankton small size fraction

Every 2-4 days (depending on the net sampling possibilities), one 50µm tucker net sample was prepared for small fraction taxonomy. For each sample, 300 copepods specimens were identified under the stereomicroscope. For each sample preserved, one other 50 µm tucker net sample was preserved for biomass measurement. The codend content was filtered through a 1000µm sieve (in order to eliminate the large organisms) then filtered through a 50µm sieve. The zooplankton was then placed on a preweighed GF/F filter that will be weighed back in Québec. Moreover, for every 50 µm sample analysed, the females *Calanus hyperboreus* and *Paraeuchaeta glacialis* were counted in one 200 µm Tucker net sample of the same cast. This counting will permit to estimate, related to the egg production rate experiments, the expected number of eggs in the 50 µm sample.

Acoustic monitoring

The Simrad EK-60 Echosounder of the Amundsen allowed our group to continuously monitor the spatial and vertical distribution of zooplankton and fish, the later mostly represented by Arctic cod (*Boreogadus saida*). The hull-mounted transducers are in operation 24h a day and will provide an extensive mapping of where the fishes are within the region of interest over a yearly cycle.

General Recommendations:

We will keep the same recommendations given on the past zooplankton team reports:

As the drift of the ship while in an ice floe can be important, we recommend sampling as often as possible with the Hydrobios and the 1-m^2 square net in the moon pool and with the ring net from the ice. Unfortunately sampling in the morning in the moon pool and from the ice in the afternoon as it was done before was not an option this leg because of the reduced team.

Low temperature is the essence of all the measurements done with live animals. The very warm temperature in our laboratory may pose problems even to the environment chamber which shows difficulties to maintain the required 0°C. The air conditioner system set at 22°C remedied to the problem. From now on, the AC should stay on and the laboratory door must remain closed. Also, the opening of the incubator should be kept to a minimum.

When the ship is in transit, and that may last a few days, and then stops in a flow, particular attention should be given to the EK-60 sounder and the ADCP in order to make sure all sensors cleared of ice before the shutting down of the engines. Otherwise the data recorded are simply unusable.

More importantly, enjoy this amazing experience in this harsh but beautiful environment, have fun and KEEP THE SPIRIT!!!

Acknowledgements. We thank the officers and the crew of Amundsen team B for their continuous effort and essential help; thank you for being able to repair or built anything we need! Special thanks to all that assisted us with sampling and digging holes in the ice and finally, to Alexis Burt who is without contest the best hoser but the worst radio holder of the leg, Dan Nguyen that provided us with litres and litres of filtered seawater, Benoit Philippe and CJ Mundy for sharing their ice algae.

2.4.2. Ice algae, Zooplankton, Ice Amphipods (CFL 3 & 4)

Participants: Stig Falk-Petersen, Anette Wold - Norwegian Polar Institute

The aim of our work is to study the effect of light on the food quality of ice algae and the transfer of energy from algae via *Calanus* copepods and ice amphipods in Arctic ecosystems in ice covered waters. We will use this to compare and contrast key ecosystem component between the Canadian Arctic and Svalbard waters, Norway. The samples collected during Leg 7 will be used by Post doc Eva Leu (ice algaes), Post doc Janne Soereide (zooplankton) and PhD student Henrik Nygaard (Ice amphipods). Sampling of ice amphipods will be continued by Haaakon Hop on Leg 9a.

Ice algae
The aim of the ice algae sampling is to study the effect of light on nutritional quality of ice algaes in terms of fatty acids and elemental stoichiometry. Samples were taken from different types of ice flows, different snow depth (high and low snow depth) one - two times a week. In total we sampled 7 times during the 5 weeks (Table 1). Three ice cores were collected at each site (high and low snow cover). The bottom 3 or 5 cm of the cores (depending on the amount of ice algaes) were cut of and kept in the dark. The cores were melted in filtered sea water; 100ml sea water was added per 1 cm core. At station D36, D38 and D41 samples were also collected from the interface between the ice and the sea water. These samples were collected by the divers using a "slurp-gun". The samples were filtered on pre-burned (450°C) GF/F 25 mm filters and frozen at -80°C. The samples will be analyzed for fatty acid composition and particulate phosphorus. Three pseudoreplicates were taken for each parameter for each core, if there was enough material. All sampling were done at the same time and location as the other ice core sampling. For details concerning the ice coring see the Ice algae report (team 3).

Zooplankton
The aim of the project is to investigate how *Calanus* spp. (focusing on *C. glacialis*) adapts to the environment in different ice conditions (Rijpfjorden, Spitsbergen pack ice vs. Canadian polynya). The following sets of samples have been taken in order to get information about the distribution of *C. glacialis* as well as the nutritional state of and their recent diet:

Vertical distribution of *Calanus* spp.
Egg production of *C. glacialis* females
Dry weight, lipid content, lipid classes, fatty acid/fatty alcohol composition, C and N stable isotope composition of *C. glacialis* and *C. hyperboreus*
Genetics

Vertical distribution of *Calanus* spp.:
Samples were taken at distinct depth using a Hydrobios. This was done by the Fortier team by Gérald Darnis. See the Zooplankton report (team 4) for more details.

Egg production:
C. glacialis females were collected from the upper 50 m by use of a ring net (from the ice edge or whole in the ice) or by use of the Tucker or Hydrobios from the moon pool. 20 healthy *C. glacialis* females were incubated in egg production chambers with *in situ* filtered sea water at 0°C temperature for3 days. The egg production chambers are equipped with mesh (1000 µm) false bottoms to separate females from eggs. After 24 hours, 48 h and 72 h we counted the eggs, measured the egg diameter, and counted the number of fecal pellets. The females were preserved in 4% formaldehyde in order to determine their gonad status. Four experiments were conducted in total.

Lipid and stable isotope compositions:
C. glacialis and *C. hyperboreus* were sampled by the Hydrobios at two distinct depths (bottom layer, below 150 m and surface layer, 50-0m). The animals were kept in the dark at *in situ* temperature and

sorted as soon as possibly after sampling. The dominant stages of *C. glacialis* and *C. hyperboreus* were selected by use of a stereomicroscope (Leica MZ6), and frozen immediately at -80° C. Samples were taken for the following parameters:
a) Dry weight
b) Lipid content
c) C and N stable isotope composition
d) Lipid class composition
e) Fatty acid and fatty alcohol composition

Genetics
Samples were collected for genetic analysis at the beginning and the end of the leg. Samples were taken with the Tucker net (200 µm) from the bottom to the surface and preserved in 90 % alcohol.

* see Zooplankton report (team 4) for more details

Ice amphipods
The aim of the study is to understand the ecology of ice associated amphipods in relation to variations in the sea ice cover and to compare and contrast the ecology and life history of ice amphipods between the Canadian Arctic and Svalbard waters.

Baited traps were deployed on ice floes either trough holes or at the ice edge of the floes. Chicken and scampi were used as bate. The divers also tried to collect amphipods with a hand net, but no amphipods were seen on any of the diving locations. The animals collected were length measured and sexed, and then frozen at -80°C. The Five individuals were pooled for each species, size group.
Samples will be analyzed for the following parameters:
population biology
genetics
lipid analyses,
stable isotope analyses

The search for amphipods were not very successful, and in total we only got 21 individuals, of which 20 was collected from one trap the first day of deployment.

The collection of ice amphipods will be continued by Haakon Hop on Leg 9a

2.4.3. Benthos (CFL 4 & 7)

Participants: Dieter Piepenburg (University of Kiel, Germany, Team 4 Food webs),
Paul Renaud, Akvaplan-niva Norway, Team 7 Carbon and Nutrient Fluxes) and
Tobias Tamelander (University of Tromsø, Norway, Team 7 Carbon and Nutrient Fluxes)

Scribe: Tobias Tamelander

Background
Benthic work on leg 7 was carried out as part of activities of Team 4 (Food webs) and Team 7 (Carbon and nutrient fluxes). This included deployments of the box corer for retrieving sediments and a Remotely Operated Vehicle (ROV) for surveys of the surface of the seafloor and epibenthos. The objectives were to determine the carbon utilisation by the benthic community as community respiration and sediment properties. This work will be continued during proceeding legs to form a time-series of the seasonal patterns of benthic metabolism.

Sampling and incubations
Sediment was collected with a box corer at four stations (Table 1) in water depths ranging from 183-469 m. Sub-cores for incubations, Chlorophyll, and CN were collected from the same box (one successful cast per station). Sub-cores for Chlorophyll *a* were sliced in 1 cm sections to 10 cm depth.

For CN, the top 2 cm were collected. These samples were frozen and transported off the ship for analyses in the home-lab.

Incubations were performed in a temperature controlled room (ca 1° C) in the zooplankton container (front deck, port side). The decrease in oxygen volume in the water overlying the sediment was measured periodically (8 h intervals) over 2-3 days. Cores containing water only acted as controls. At the end of the incubations, the sediment sieved on 0.5 mm mesh sieve and the fauna collected for analyses of species composition, abundance and biomass. SOD was also measured in cores to which algae from the sub-ice layer had been artificially introduced. Experiments with algal additions were only performed at two stations.

The ROV was deployed 3 times (Table 2). During dives #4 and #6 it was possible to survey the benthic habitat and the epifauna in transects and obtain video-recorded material for quantitative determinations of the epifauna. Strong ship-drift during dive #4 caused heavy resuspension of the sediment, precluding detailed photography of the epifauna and transect for spatial coverage of epifauna.

Preliminary results
The sediment generally consisted of a brown top layer, ca 5 cm deep, and a deeper layer consisting of grey clay. Small stones were abundant at Stns D34 and D35. At Stn D37 and D39 the sediment and the clay was softer and contained less stones. Some fauna was visible in all cores (polychaete tubes, clam siphons protruding from the sediment).

The raw values of oxygen consumption (sediment and water) ranged from 1.4 to 2 mmol O_2 $m^{-2}d^{-1}$ at the stations assessed. Oxygen consumption was increased after algal additions at least at one of the stations.

2.5. Team 6

PIs: Tim Papakyriakou (U of M), Lisa Miller (IOS) and Jean-Louis Tison (Ulb – Belgium)

Participants: Tim Papakyriakou (U of M), Bruno Delille (Ulg – Belgium), Melissa Chierici (Göteborg University – Sweden), Agneta Fransson (Göteborg University – Sweden), Gauthier Carnat (U of M) and Doris Leong (Dalhousie)

Introduction
The main goal of Team 6 is to investigate the sea-ice-atmosphere exchanges of climatically active gases (such as carbon dioxide and dimethyl sulfide). Gas concentrations and near-surface fluxes are measured from installations on the ship and from the sea ice. In order to better understand the driving

factors regulating those exchanges, we are looking at ice and water biogeochemistry, selecting a set of variables that describes the best ice and water column conditions in terms of physical, biological and chemical properties. Meteorological and surface climatological data are also collected to relate the observed fluxes and ice/ocean properties to near-surface microenvironment. Collectively this information should provide a good description of the gas cycles and their dynamics in the arctic environment of the flaw lead system over the annual cycle.

Sampling and deployments were undertaken as part of CFL Drift Mode – where the ship would associate itself with an ice floe for a period of time ranging from 4 d to 17 d. Our sampling, monitoring and the associated data set is described in the following sections.

2.5.1. Surface Meteorology and Flux Project

Introduction

The surface meteorology and flux program (CFL Team 6) is designed to record basic meteorological conditions and to study exchanges of momentum, heat and mass across the atmosphere-sea ice-ocean interface. The main value of this program to the overarching objectives of Team 6 is the direct measurement of CO_2 fluxes and measures of the basic terms of the heat budget (sensible and latent heat, radiation fields).

Turbulent fluxes (CO_2, heat and momentum) are measured by the eddy covariance technique, which is dependent only on atmospheric measurements. To realize the potential of the data set the measurements of the CO_2 flux, in particular, require ancillary information on processes (physical, biological and chemical) that drive gas exchange. In an open-ocean situation this context is largely provided by measurement of sea-surface pCO_2, but the situation becomes much more complex when a sea ice cover is included in the equation. Surface flux monitoring facilities are deployed on the ship`s foredeck, and when possible, on the sea ice.

This section of the CFL Team 6 cruise report reviews the atmospheric and sea surface pCO_2 measurements that were made during Leg 7. Other sections of the report will deal with the sea ice measurements that were made in support of the CO_2 flux measurements.

Ship-Based Micrometeorology and Eddy Covariance Flux Tower

Methods

The micrometeorological tower located on the front deck of the Amundsen (Figure 1.1) provided continuous monitoring of meteorological variables and eddy covariance parameters. The tower consists of slow response sensors that record bulk meteorological conditions (air temperature, humidity, wind speed/direction, surface temperature) and fast response sensors that record the eddy covariance parameters (CO_2/H_2O concentration, 3D wind velocity, 3D ship motion, air temperature) (Table 1.1). In addition, radiation sensors (Figure 1.1, Table 1.1) were installed on the roof of the wheelhouse to provide information on incoming radiation fields, including: long-wave, short-wave, photosynethetically active, and ultra-violet radiation (UVA and UVB). All data was logged to Campbell Scientific dataloggers; a model CR5000 logger was used for the eddy covariance data, a CR1000 logger for general meteorological elements (e.g., temperature, relative humidity, etc.), and a CR23X for the radiation data. All loggers were synchronized to UTC time using the ship's GPS system as a reference.

The eddy covariance system on the tower makes use of two separate gas analyzers and a single 3D sonic anemometer. The dual gas analyzers system allows us to make use of both closed path and open path eddy covariance systems. The open path gas analyzer has the benefit of making measurements concurrently with the sonic anemometer, but the closed path gas analyzer is not as easily disturbed by adverse weather conditions.

In order to make sure that the two systems are comparable, careful calibrations were performed on both instruments. The closed path system is based on a LI-7000 gas analyzer which employs two optical cells, one of which was used to monitor the drift of the instrument by constantly passing a stream of ultra-high purity N_2. In addition, the sample cell of the instrument was calibrated daily using the ultra-high purity N_2 to zero the CO_2 and H_2O measurements, and a reference gas of known CO_2 to span the instrument. Occasionally, a span calibration of the H_2O sensor was performed using a dew point generator (model LI-610). The open path gas analyzer (LI-7500) could not be calibrated as conveniently, and so it was calibrated approximately every three weeks. In general, we find that this is effective for this particular instrument, which does not drift significantly over time.

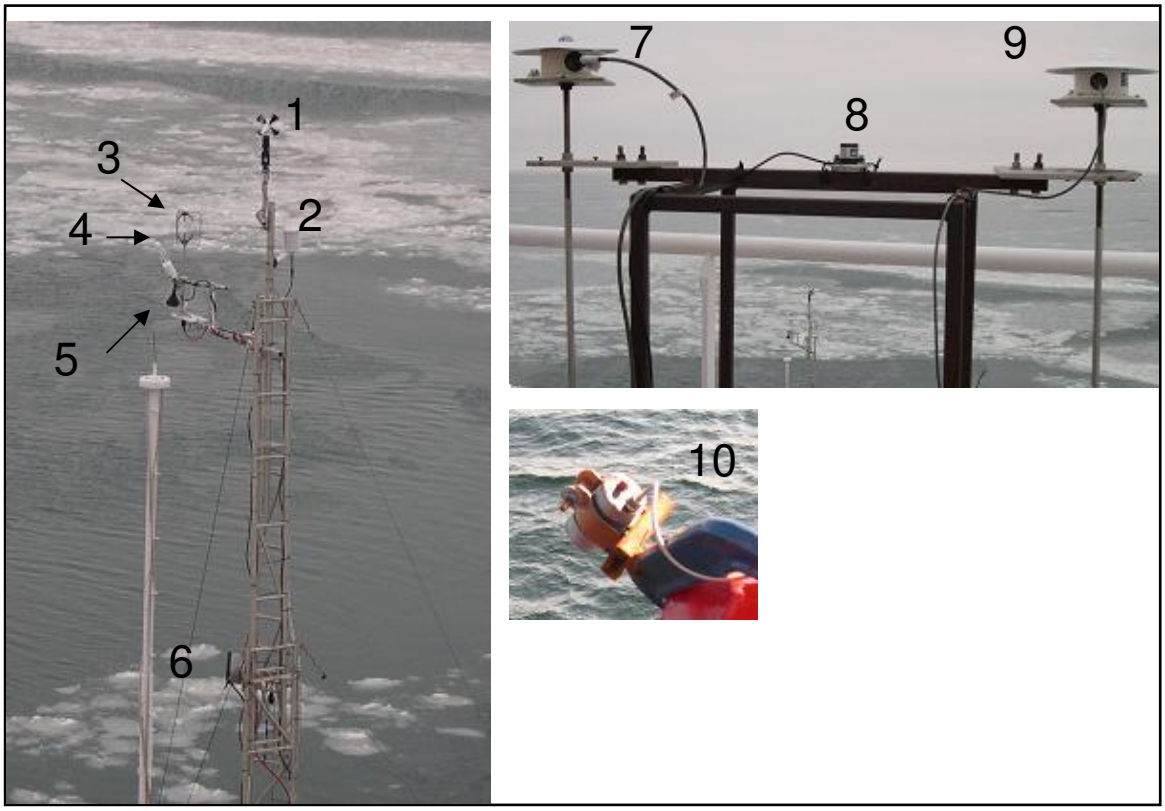

Figure 1.1: Meteorology and flux program instrument setup. See Table 1 for description of instruments based on the numbers. Note that on Nov. 18 the Motion Pak (6) was moved to the rear face of the tower to facilitate easier motion correction, and the UV sensor is not shown.

Table 1.1: Description of instruments shown in Fig. 1.1.

Sample data

As an example of the slow response meteorological data, Figure 1.2 shows the evolution of air temperature and wind speed over one day at Station D7 (a first year sea ice floe, ~70cm depth). An example of the rapid response flux data is shown in Figure 1.3, which shows 10 minutes of vertical wind speed and CO_2 concentration. A great deal of processing will be required to calculate actual fluxes of CO_2, and to filter out erroneous data.

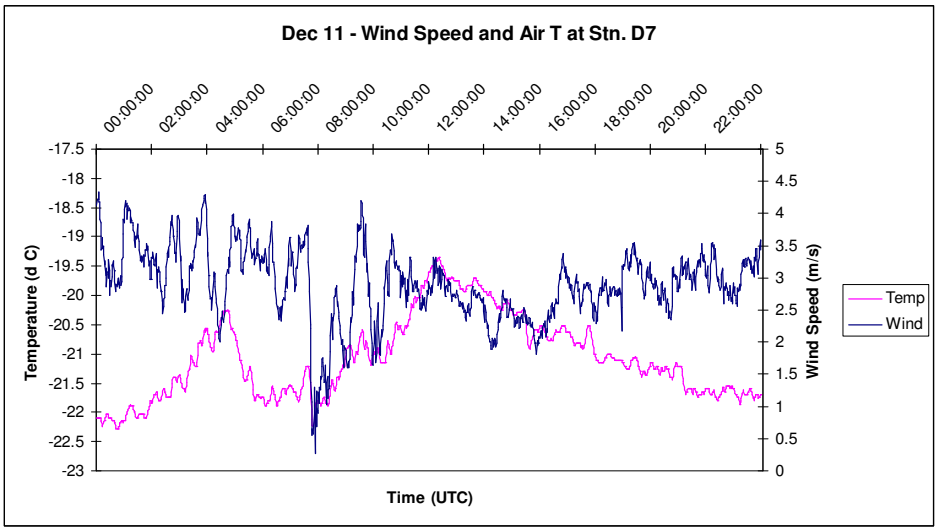

Figure 1.2: Slow response meteorological data example; wind speed and air temperature (24 hrs).

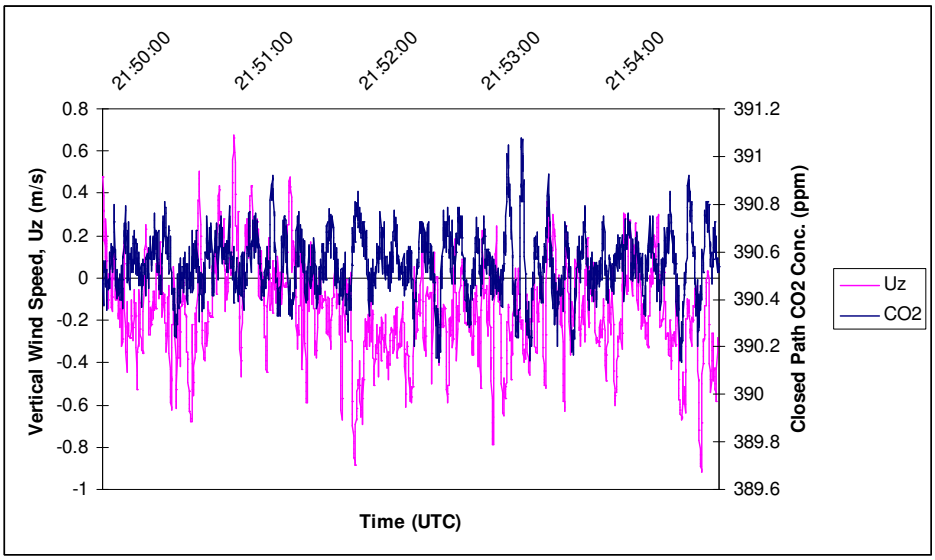

Figure 1.3: Fast response flux data example; vertical wind speed and closed path $_{CO2}$ concentration (10 min).

Notes

The meteorological tower ran consistently for the duration of the leg with the exception of brief periods when the tower was taken down for maintenance. Occasional periods occurred when the LI-7500 and sonic were inoperable because of ice and frost. This problem most seriously affected the LI-7500, which was very difficult to keep clean. The problem also affected the sonic anemometer, but to a much lesser degree. The extent of data lost due to atmospheric conditions cannot be estimated at this time, and will only be known once post processing is complete.

Ice-Based Micrometeorology and Eddy Covariance Flux Tower

Methods

An ice-installation (Figs. 1.4 a and b) was installed on April 16. A list of variables that were monitored appear as Table 1.2.

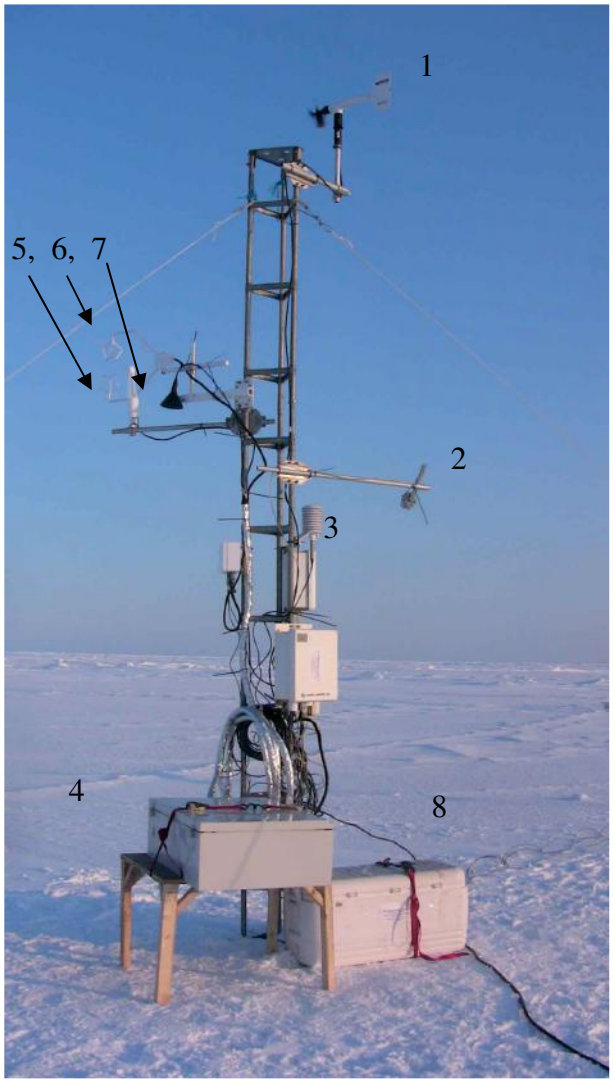

Figure 1.4a: Meteorology and flux instrument setup on sea ice. See Table 1.2 for description of instruments based on the numbers. Item 8 is the 12VDC power supply.

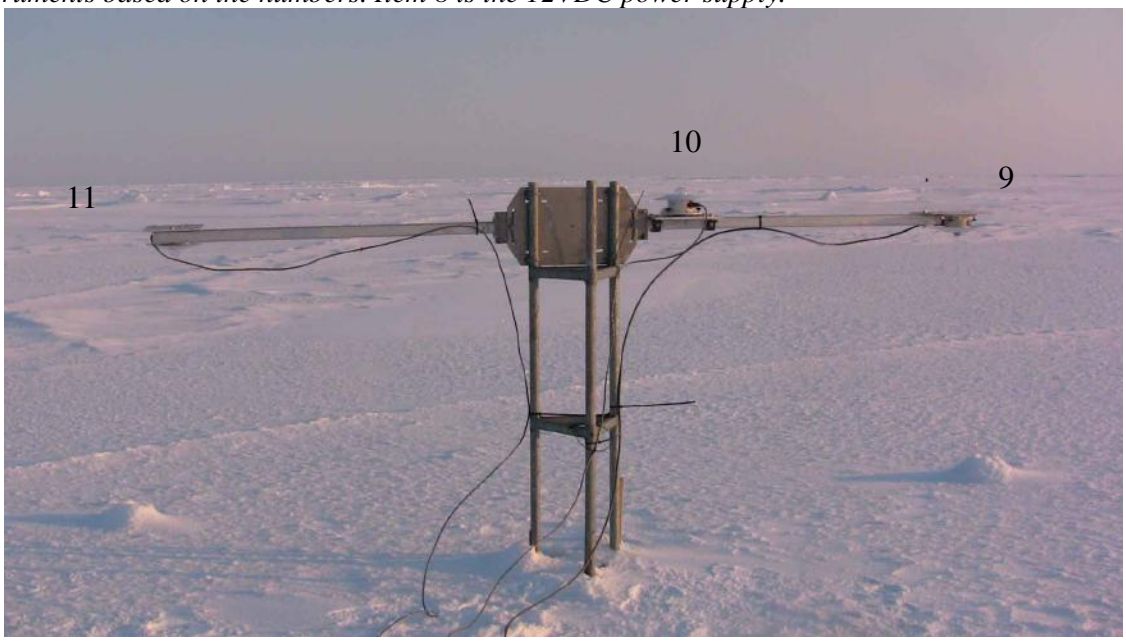

Figure 1.4b: Radiation sensors on sea ice. See Table 1.2 for description of instruments based on the numbers.

The installation was located approximately 500 m to the east of the ship on a uniform pan of sea ice that was 1.32 m thick at the time of installation. The set-up consisted of two short TV antenna-style tower sections: i) for surface fluxes and meteorology (Fig. 1.4a), and radiation (Fig. 1.4b). Snow thickness was on average 5 cm, until a snow event on April 21, increasing the snow depth around the tower to approximately 10 cm. The installation was powered by lead-acid batteries (12 VDC), which themselves were trickle charged by a battery charger which required AC power to the site. A 10kW diesel generator was located 200 m to the north of the tower. The vertical structure of ice temperature was monitored by thermocouples arranged in profile within a shield (Fig. 1.5) composed of concentric pvc tubing (OD nominal 3 cm). Signals associated with the set-up logged by a Campbell Scientific loggers: model CR1000 for basic meteorology and temperature, and model CR3000 for the components of the eddy covariance system. Raw data from the flux sensors were sampled at 20Hz and immediately transferred to flash card.

Notes

The towers, complete with meteorological and radiation sensors were deployed on April 16, except for incoming solar radiation (April 18). The sonic anemometer and open-path flux components were installed on April 19, and the closed sensor was installed on April 22. The LI-7500 was factory calibrated prior to deployment. The zero and span of the LI-7000 was checked prior to deployment, then again on April 21. There are several notes related to this sensor. First, the enclosure temperature rose to nearly 50C with full insulation. Insulation was removed on April 21 and temperature subsequently dropped to 17C (nominal). Second, it is difficult to field calibrate the sensor. Alternatively, span and zero gas were passed through cell B at ~ 0.4 L/min. Cell pressure increased to slightly greater than ambient atmosphere.

Figure 1.5: Temperature sensor prior to installation. Sensor levels are provided in Table 1.2.

Table 1.2: Description of instruments shown in Fig. 1.4a and b.

On-track *p*CO_2 System

Methods

A custom-built *p*CO_2 system was utilized on this leg to measure dissolved $_{CO2}$ at the sea surface in near real time. The system (Figure 1.6) is located in the engine room of the Amundsen, and draws sample water from the ship's clean water intake. The water is passed into a sealed container through a shower head, maintaining a constant headspace. This set up allows the air in the headspace to come into equilibrium with the CO_2 concentration of the seawater, and the air is then cycled from the container into the LI-7000 gas analyzer in a closed loop. Thermocouples are used to measure water temperature immediately before entering the equilibration chamber, and to measure the temperature of the air in the chamber. All data is logged to a Campbell Scientific CR1000 datalogger.

The LI-7000 gas analyzer was calibrated daily using ultra-high purity N_2 as a zero gas, and a gas with known CO_2 concentration as a span gas. Spanning of the H_2O sensor was not necessary because a desiccant column removes H_2O from the air stream before passing into the sample cell. As with the closed path system, a stream of N_2 is constantly cycled through the reference cell of the LI-7000 to monitor and correct for drift of the instrument.

Figure 1.6: The on-track pCO_2 system located in the engine room of the Amundsen. The equilibration chamber is the clear cylinder (left bottom) and the gas analyzer is the box with the digital display.

Sample Data
Figure 1.7 shows an example of a single day of CO_2 data recorded by the on-track system, along with water temperature. Further processing must still be undertaken to correct the values for changes in temperature that occur due to the length of the sample line, and to properly calculate pCO_2.

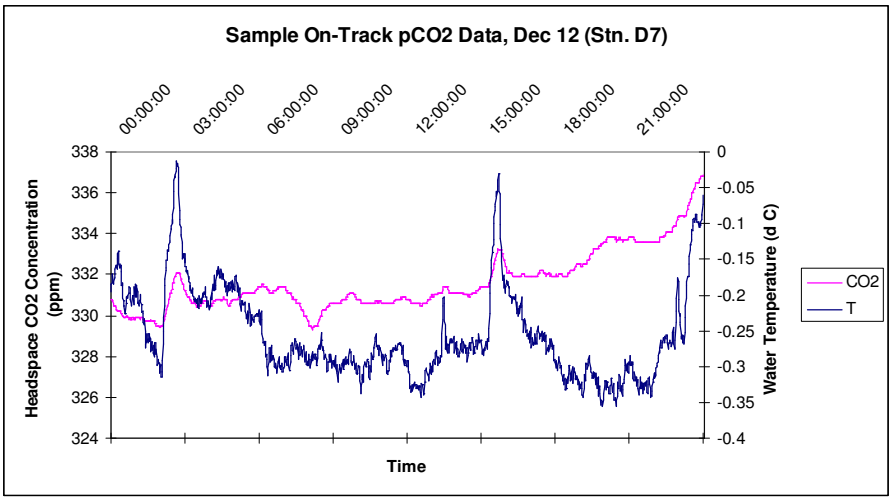

Figure 1.7: Sample on-track pCO_2 data (CO_2 and water temperature)

Notes
The on-track pCO_2 system was active for the duration of the leg, with some minor interruptions for maintenance. Major interruptions in data collection were experienced when the ship was breaking ice, which either reduced the flow of water into the equilibration tank, or completely blocked it. In the case of blocked flow, the data is lost, but tests will have to be conducted to determine if data obtained with low water flow is useful. Also note that the air outlet from the closed loop clogged, increasing cell pressure to ~ 139 kPa, and causing the water in the reservoir to rise to dangerously high levels. The symptoms are: i) reduced air flow rate in the closed loop; ii) high cell pressure and water level. To remedy the situation the reservoir must be removed from the system so that the outlet can be removed and cleaned. Note, the reservoir need not be dismantled. A temperature sensor was installed into the reservoir to monitor water temperature. Temperatures are generally similar to the temperature that is measured at the tank inflow.

2.5.2. CO_2 In Sea Ice

Bulk sea ice CO_2 contents

Sea ice CO_2 contents were measured by two ways :
-Ice core collections for further gas chromatography analysis
-Peepers

Gas chromatography measurement
Ice cores were collected from further measurements of pCO_2 of bulk sea ice at high vertical resolution. pCO_2 will be measured with a 5 cm vertical resolution using a new method developed by Verbeke (2005). The backbone idea of this method is that the ice samples are equilibrated at *in situ* temperature in an enclosure filled with a standard atmosphere of known concentration in CO_2. After equilibration, CO_2 concentration in the enclosure is analysed by gas chromatography.

Peepers
Material and methods

A peeper is a 20 cm length closed tube formed by a silicone membrane permeable to CO_2 exchanges (Fig. 2.1). The top part and the bottom part of the tube are impermeable (aluminium sheets). Stainless steel tubings with Swagelock fittings are used to pump and inject air inside of the tube.

The idea is to install the peeper in the ice structure by drilling a hole with a small auger and to leave it there for a couple of days (the top part of the hole is closed by a wooden plate to avoid air exchanges with the atmosphere). After 24 h, the pCO_2 of the air in the inside volume of the peeper is supposed to be in equilibrium with the pCO_2 of the medium surrounding the peeper. The air volume of the peeper is then pumped in the field and analyzed with a LICOR.

Deployment strategy

There are two ways to install the peepers in the ice. The first one is to drill a sac hole at the desired depth. The second one is to drill through the seawater. The mediums surrounding the peepers are thus considerably different: frozen brines in the first case, frozen seawater in the other case.

We deployed seven peepers in total at one station. Three in the same « through seawater hole » at respectively 20 – 40 and 60 cm depths (for a total ice thickness of 160 cm). The four other ones were put into sac hole at 20 (2 peepers) -40 and 60 cm depth as well for comparison purposes. The peepers were sampled every four days.

Fig. 2.1 Peeper and installation

Preliminary Results

The pCO_2 levels measured with the peepers at 20 cm depth in sac holes.

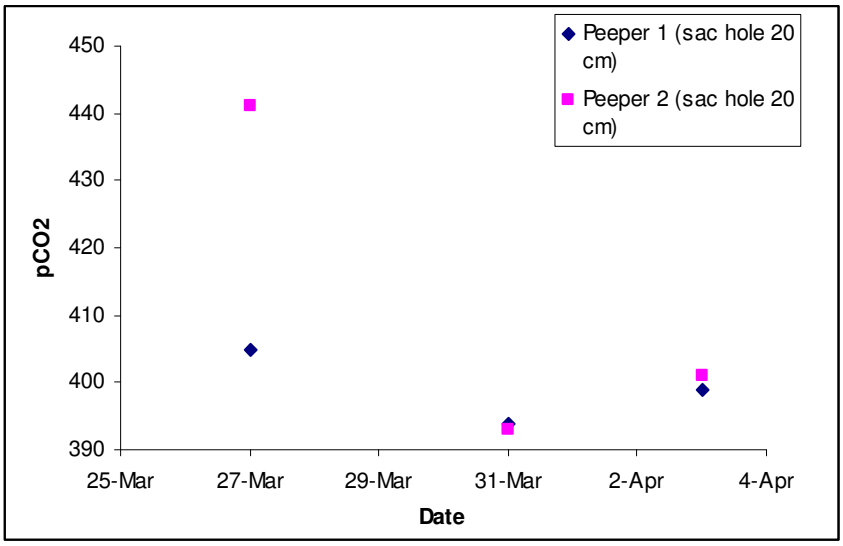

Fig. 2.2 Changes in peeper pCO_2 with time after deployment.

pCO_2 in Brines and Surface (under-ice) Water

SIES System

Material and methods

Sampling of ice brines was conducted by drilling shallow sackholes (ranging from 15 cm down to almost full ice thickness) through the surface of the ice sheet. The brine from adjacent brine channel and pockets was allowed to seep into the sackhole for 15-60 min, with the hole covered with a plastic lid (Gleitz et al., 1995), reportedly the best current method to sample brines for chemical studies (Papadimitriou et al., 2004). Water was pumped from the hole using a peristaltic pump (Masterflex® - Environmental Sampler) and supplied to the sea ice equilibrator system (SIES), a device for measurements of pCO2 and air-ice CO2 fluxes. This device allows measurement of pCO2 using a membrane contractor equilibrator (Membrana® Liqui-cell) coupled to an infrared gas analyzer (IRGA, Li-Cor® 6262). Seawater flowed into the equilibrator at a rate of 1 L min-1 and a closed air loop ensured circulation through the equilibrator and the IRGA at a rate of 3 L min-1. Temperature was measured simultaneously in situ and at the outlet of the equilibrator using Li-Cor® sensors. Temperature correction of pCO2 was applied assuming that the relation from Copin-Montégut (1988) is valid at low temperature and high salinity. The IRGA was calibrated soon after returning to the ship while the analyser was still cold using CO2-in-air standards with mixing rations of 0 ppm and 369.4 ppm of CO2 supplied by Air Liquide Belgium®. Stable field pCO2 readings usually occurred within 5 min of flowing gas into the IRGA. The equilibration system ran 10 min before averaging the values given by the IRGA and temperature sensors over 30s and recording the averaged values with a data logger (Li-Cor® Li-1400). All the devices were enclosed in an insulated box that contained a 12V power source and was warmed to keep the inside temperature just above 0°C.

Preliminary results

During leg 7b, pCO_2 within sea ice brines were always oversaturated compared to the atmosphere. pCO_2 within brines ranged from 480 to 1880 ppmV. The upper end of this range corresponds to the highest pCO_2 values ever measured within sea ice (by a direct method). Previous largest value of pCO_2 observed within warmer sea ice (i.e. -9°C) was around 900 ppmV. This confirms that decrease of temperature acts to increase pCO_2. Higher pCO_2 was observed in the upper, saltier and colder part of the ice cover. We observed a high spatial and temporal variability, that is not related to sea ice temperature.

Comparison of the last two stations (16/04/08 and 19/04/08) gives some insights on short term variability. pCO_2 dropped from 1130 to 480 ppmV in the lower 40 cm of the ice (Fig. 2.3). Similar salinity and temperature together with the occurrence of platelet in the skeletal layer, suggest that the ice was in a "steady" of " growing" state. Thus, this drawdown should be ascribed to the algae bloom (chl a µg increased from 12 to 256 µg L^{-1}), underlying the role of the primary production on CO_2 dynamics within sea ice.

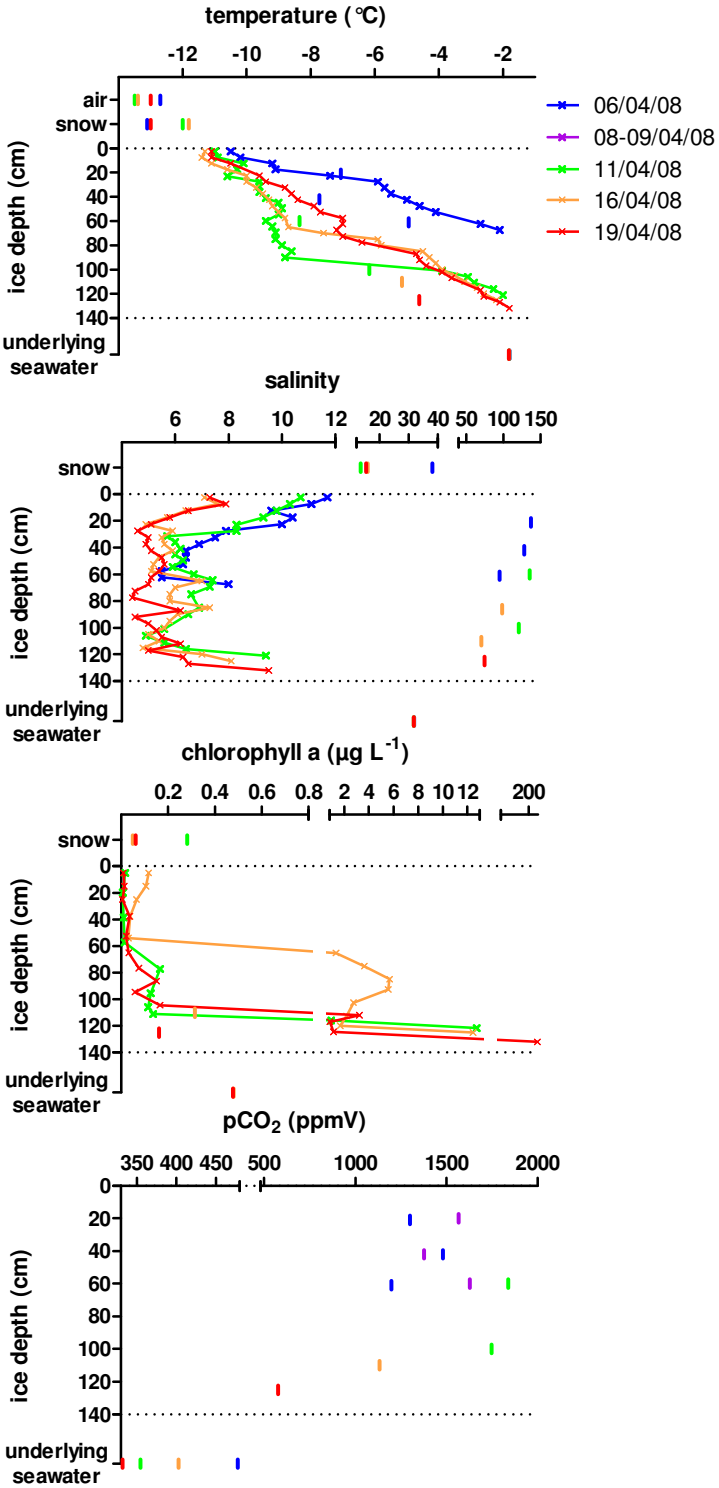

Figure 2.3 . Temperature, salinity, shlorophyll a and pCO_2 , within snow (vertical bars), ice (line with crosses), brines (vertical bars), and underlying water (vertical bars) during leg 7b

Gas chamber measurements

Material and methods

A chamber (Fig. 2.4) coupled to the SIES was used to measure air-ice CO_2 fluxes. The accumulation chamber (West system®) is a metal cylinder closed at the top (internal diameter 20 cm; internal height 9.7 cm). A rubber seal surrounded by a serrated-edge iron ring ensured an air-tight connection

between the base of the chamber and the ice. For measurement over snow, an iron tube was mounted at the base of the chamber to enclose snow down to the ice and prevent lateral advection of air through the snow. The chamber was connected in a closed loop between the air pump (3 L min^{-1}) and the IRGA of the SIES. The measurement of pCO_2 in the chamber was recorded every 30 sec for at least 10 min. The flux was computed from the slope of the linear regression of pCO_2 against time ($r^2 \geq$~ 0.99) according to Frankignoulle (1988). The uncertainty of the flux computation due to the standard error on the regression slope is on average ±3%. CO_2 fluxes values correspond to the average of three measurements. The idea is to look at the changes in the pCO_2 between the beginning and the end of the gas chamber deployment. Any increase in this pCO_2 can then be understood as a positive flux from the ice – any decrease as a negative flux. The gas chamber is usually left on the ice for a period of time of 10 minutes.

We did several gas chamber measurements during the main coring stations but also during small punctual stations. In order to investigate the influence of the ice properties on the fluxes, we put the chamber on different ice types and thicknesses.

Fig. 2.4 Gas chamber on top of 70 cm thin ice with frost flowers on top

Preliminary results

One of our interests is to look at the impact of the snow cover on the gas exchanges measurement. The next two charts (in Fig. 2.5) show the pCO_2 changes in two gas chamber experiments on the same spot. The first one was put on top of the snow, the second one on the ice with the snow cover removed.

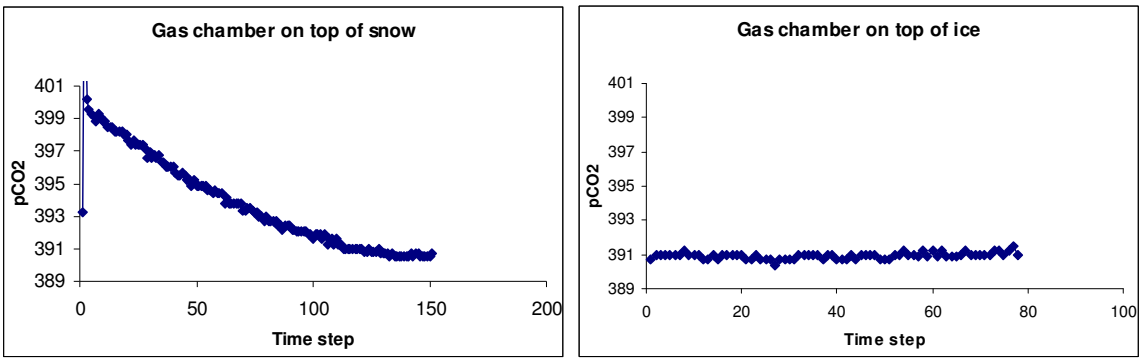

Fig. 2.5 Rate of gas concentration change in surface chambers.

Air-ice CO_2 fluxes were close to zero or around the detection limit during the leg 7b. This is not surprising since the snow-ice interface temperature ranged from -12.7 to -10.5°C, likely below the temperature threshold of permeability for gases within sea ice. However, we observed some fluxes between the snow and the atmosphere that indicate that specific processes could affect CO_2 concentration within the air trapped among snow crystals. Indeed, the salinity of the snow was significantly higher than the salinity of the upper part of the ice cover as a probable consequence of previous formation of frost flowers. This high salinity could provide a CO_2 buffer capacity to the snow

that supports interaction between snow and CO_2. In addition, algae biomass of the snow is also significantly higher than the upper part of the sea ice cover. This biomass may also play a role in these snow processes.

2.5.3. DMS/P/O In Sea Ice

DMS/P/O contents in sea ice, brines and water

Material and methods
The purpose of the DMS/P/O project is to measure the DMS/P/O contents in sea ice, brines and water during leg 7 in order to determine the dynamics of those compounds in the ice and between the mediums. Another point of interest is to follow the evolution of those concentrations over time and to look at the potential interactions and influences of the biogeochemistry of sea ice on DMS/P/O. The work is undertaken in collaboration with Dr. Maurice Levasseur (U.Laval).

Basically, we took ice cores, brines and water samples at different locations representing different ice types and thicknesses. Ice samples were taken using a electropolished stainless steel corer and liquid samples were put into air tight vials with the help of a peristaltic pump or syringes. The vials stayed in the dark at 4 degrees before analysis to avoid biological activity. The ice cores were immediately cut in the freezer room on the ship into 5 cm length sections. Each section was then crushed in a stainless steel air tight container using an ice crusher. After that, the container was connected to a « Purge and Trap » system. This system uses helium as a carrier gas to remove all the DMS from the container and to accumulate it into a teflon loop immerged into liquid nitrogen in order to capture the DMS. When all the DMS is trapped (10 minutes are needed to extract all the DMS from the container), the loop is put into hot water and all the gas is released into a gas chromatography system (GC Varian with a six way valve, a column specific for sulfur and a PFPD detector) – Fig. 3.1. The crushed ice is then put into vials for DMSP and DMSO further analysis. In order to measure the DMSP levels of the ice, we added two pellets of NaOH in order to transform the DMSP into DMS. The ice was then stored at 4 degres in the dark for 12 hours to melt and mix the ice with the NaOH.

Liquid samples (DMSP and water/brines samples) are also analyzed with the Purge and Trap system and the GC. The only difference is that the sample is injected with a syringe into a glass tube instead of in the stainless steel container. DMSO vials were not analyzed on the ship, and instead will be shipped to Belgium for processing.

Fig. 3.1 Purge and trap system and ice crusher

Preliminary results
Leg 7 was a very interesting leg in terms of DMS/P/O measurements because of the phytoplanctonic bloom that occurred at the beginning of the leg. The two next charts (Fig. 3.2) show the DMSP profiles in ice for one station before the bloom and one station after the bloom.

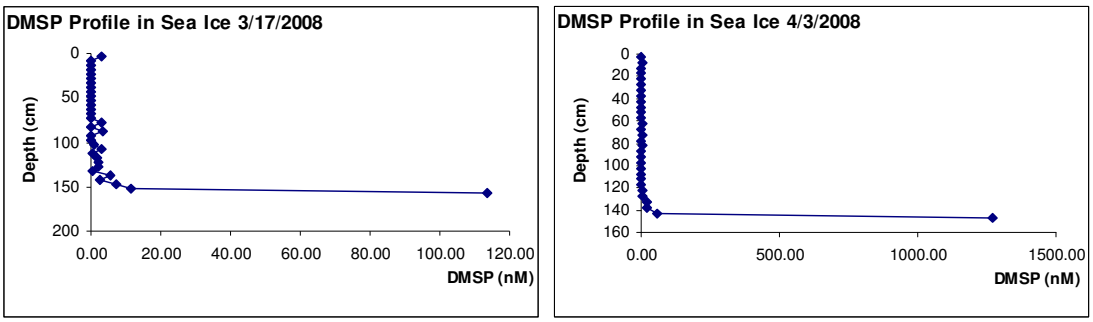

Fig. 3.2 DMSP profiles in sea ice.

Cell lysis during a dilution experiment and related DMSP release

Material and methods

In collaboration with Dr. C.J. Mundy and the dive program we collected underice water and brines at different locations. The brines or underice waters were then distributed in different quantities (starting from 100 ml to 2 ml) into whirlpack bags. The next step was to add different quantities of milliQ water into those bags in order to create a dilution gradient in terms of salinity. We used two techniques for that. The first one was a fast mixing technique : the milliQ water was just added to the bag. The second one was a slow mixing technique : a frozen block of milliQ water was slowly melted into the brines or water samples. Both techniques required 12 h of mixing in the dark to avoid biological activity.

The purposes of this experiment are to show how cell lysis provoked by an osmotic choc can affect different compounds and to look at the rate this osmotic choc and those cell lysis are occuring. To investigate that, we did nutrients, chla, DMSP and salinity measurements on the samples. As a intracellular compound and osmoregulator DMSP is supposed to react strongly to any change in the salinity of the medium.

Preliminary results

Most of the results aren't available yet but we were already able to show that the amount of DMSP in a diluted sample was approximately two times longer than in a normal sample.

2.5.4. Ice Permeability

Bail test

Material and methods

The bail test has been often used in soils studies and a few times successfully used in sea ice studies. The purpose of this test is to derivate the permeability of the ice from the rate of penetration of sea water into a sac hole. After drilling a hole in the ice close to the bottom (usually between 2 and 10 cm of ice are left at the bottom), a tube is inserted into the hole and a floater is inserted into the tube. A laser, mounted on the top of the tube is measuring the distance between the floater (indicating the water level in the hole) and the top of the tube. The water level is increasing into the hole by addition of sea water coming through the ice. The difference between the water level at equilibrium and the water level at any time is then put on a chart and the exponent of the exponential curve obtained gives the permeability.

Miscellaneous

Even if the bail test was working perfectly during the tests and the calibrations we did on the ship, we had some difficulties during the experiments in the field. We undertook four unsuccessful tries in total and we were not able to get a stable and reliable curve during one of those tries. Considering the

results obtained, the test seems to work for a short time but then something that we were not able to find is disturbing the signal. Fig 4.1 illustrates such an example.

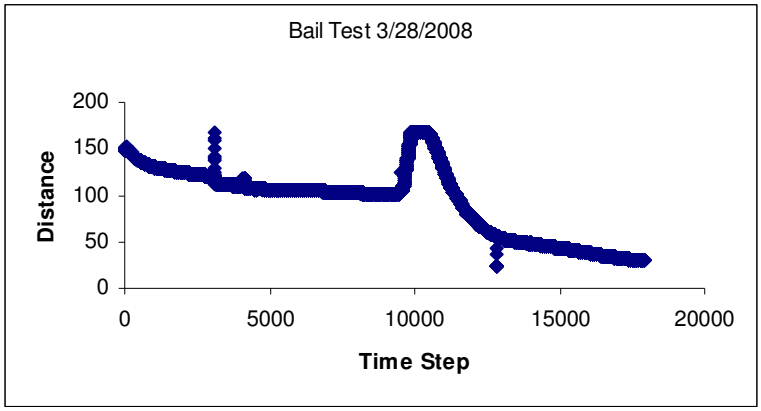

Figure 4.1 Sample bail test results.

Another problem relates to a contribution of brine to the test hole. To avoid that, we unsuccessfully tried to build a rubber jacket around the basis of the tube. But the salinity levels measured into the hole remained still higher than a normal water signal.

2.5.5. Sea Ice Biogeochemistry

In-Situ measurements and Ice Core Collection

In order to get a set of biogeochemical variables that will help us to understand the dynamics of the processes happening in sea ice, we collected ice cores for further analysis in both Winnipeg, Brussels and Liege labs. Basically, we took between 10 and 12 cores at each station. A major concern throughout the whole sampling procedure has been to prevent contamination in trace metals, especially iron. We followed the trace metal clean procedures proposed by Lannuzel et al. 2007. Nitrile gloves were used for handling the iron dedicated samples, and items used for sample collection and storage were acid-cleaned and sealed in plastic bags. The electropolished stainless steel core barrel (Lichtert Industries, Brussels, Belgium) has been specially designed and tested to be non-contaminant for iron. Seawater was pumped up with a portable peristaltic pump (Cole-Parmer, Masterflex E/P). Finally, the sea ice cores dedicated to iron determination were immediately packed in cleaned plastic bags and stored at minus 25 degrees Celsius.

In addition to that, we measured a couple of standard variables in the field (e.g. : freeboard, snow thickness, snow temperature...).

A complete list of the variables that will be accessible for the leg 7a is presented in Table 5.1.

Table 5.1 Biogeochemical parameters measured during leg 7.

2.5.6. Dissolved Inorganic Carbon (DIC)/Alkalinity Project

DIC and TA in sea ice, brines and under-ice water
Brines were collected for onboard measurements of dissolved inorganic carbon (DIC) and total alkalinity (TA). Sackholes were drilled at several depths, depending on ice thickness and temperature. Samples were collected for DIC/AT as well as C-13. In some cases where brine formation was limited, the sampling priority was DIC, AT, then C-13, from highest to lowest. Temperature was measured in-situ, and salinity later measured in the lab. During Leg 7a, pH was also measured.

Analysis for DIC and TA was performed using the VINDTA 3C (Versatile Instrument for the Determination of Titration Alkalinity) developed by Marianda, (Fig. 6.1).

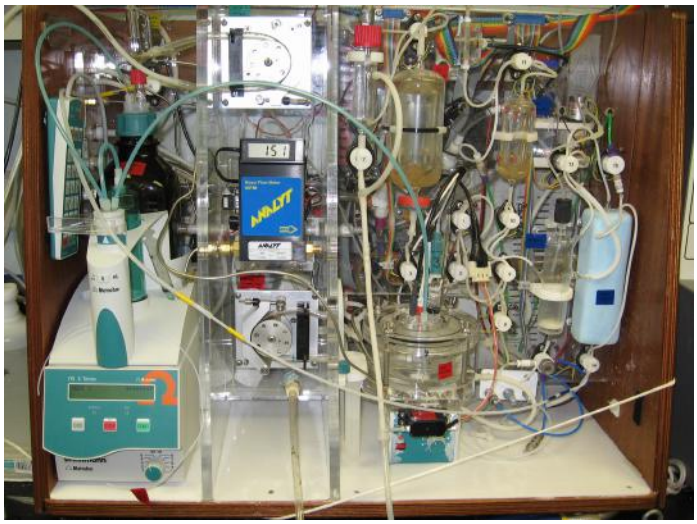

Figure 6.1 VINTA System.

TA was determined by titrating a volumetrically accurate subsample using HCl as the titrant, and a set of three electrodes - a Ross pH electrode, a reference AgCl electrode and an auxiliary platinum electrode. For measuring DIC, a volumetrically determined subsample was acidified with 8.5% H3PO4 to convert all inorganic carbon into gaseous CO2. The CO2 was stripped out of the sample using ultra-pure N2 gas, transferred into a coulometric titration cell and detected using the coulometric method.

DIC and TA in the water column
DIC/AT was sampled coincident with nutrient sampling, at the same depths/bottles. These nutrient casts occurred approximately every 6th day during Leg 7a and every 3rd day during Leg 7b. For Leg 7a, additional samples were also taken for time series measurements. In particular, around the 27-28th of March, biological production was initiated according to Chl a and fluorescence measurements. Samples were then taken in order to observe corresponding changes in DIC.

Water for DIC/AT measurements were sampled in 500mL bottles, then spiked with 500uL HgCl2 in the lab in order to avoid contamination of the Rosette area. The samples were stored in the dark at 4C until analysis. Surface water samples were also collected at the ice-water interface. These complement rosette sampling since the CTD is deployed through the moon pool of the ship and cannot sample the upper part of the water column.

High vertical resolution of DIC, TA and calcium carbonate content of brines
Ice cores were collected from further measurements of DIC, TA and calcium carbonate content of brines at high vertical resolution. The cores were sectioned into 10cm pieces and placed into gas impermeable Tedlar bags. These bags have a small valve from which air is removed using a vacuum

pump and the ice melts overnight at room temperature. From all melted ice cores, we measured DIC, AT, pH and salinity, and for the gas in the Tedlar bags (after melting of ice) we measured pCO2.

Brines will be extracted by centrifugation from the ice cores with a 10 cm vertical resolution. DIC and TA will be analyzed accordingly to the methods described above.

7.4 Sampling Dates/Stations

Station	Date	Notes
D29	March 17	rosette(bottom depth 312m)
D31	March 21	cage sampling of thin ice(30cm); surface water
D32	?	ice core sampling while stuck in ice: 150-157cm(thick ice)- 5 cores 50-55cm(thin ice)-7 sampling occasions w/8 cores
D33	March 24, 27, April 1	rosette time series(bottom depth 188m); ice cores: 50 cm and 145 cm
D35	April 2	rosette(bottom depth 213m)
D36	April 6,7	rosette(bottom depth 274m); surface water; 3-levels of brine
D37	April 10	rosette(bottom depth 278m)
D38	April 11,13	surface water; 2-levels of brine(60, 100cm)
D40	April 15	rosette(bottom depth 477m)
D41	April 16,18, 19, 21	2 rosettes(bottom depth 486m); 3 levels of brine(120, 100, 50cm) + surface water; 3 levels of brine(120, 90, 50cm) + surface water

*Note that during Leg 7a, station numbering differed between ice core stations and rosette stations.

**The following Leg 7a activities have yet to be logged by station and date (to be completed by Chierici & Fransson):
Brine from thick and thin ice (20, 30, 40, 80cm)
Frost flowers: 4 samples
Surface water (0, 2, 5m): 4 sampling occasions with pump
Under-ice water: used with pump and arm. 2 sampling occasions
C13 sampling 1 ice core (thick), 1 ice core (thin), brine (40cm)
Syringe sampling for DIC and pCO2 on GC: brine (10, 20, 30, 40, 80cm)

2.6. Team 7

2.6.1. Carbon & nutrient fluxes

PI: Jean-Éric Tremblay (Department of Biology, Laval University)
Participant: Jonathan Gagnon (Department of Biology, Laval University)

Rationale. The Arctic climate displays high inter-annual variability and decadal oscillations that modulate growth conditions for marine primary producers. Much deeper perturbations recently became evident in conjunction with globally rising CO_2 levels and temperatures (ACIA 2004; Comiso

2003). The thickness and extent of Arctic sea-ice decrease rapidly (Johannessen et al. 1999; Rothrock et al. 1999) and the ice-free season is extending both in the Arctic (Laxon et al. 2003) and subarctic (Stabeno & Overland 2001). Models predict further reductions in ice cover (ACIA 2004). These changes entail a greater penetration of light into surface waters, which is expected to bolster phytoplankton production (Rysgaard et al. 1999), food web productivity and CO_2 drawdown by the ocean. At present, phytoplankton production varies by two orders of magnitude across the Canadian Arctic, but the forcing mechanisms are poorly understood and quantified. In the Canadian Archipelago, the productivity of phytoplankton is likely to be limited by light or the supply of allochtonous nitrogen, depending on ice conditions. The supply of allochtonous nitrogen is influenced by climate-driven processes, mainly the large-scale circulation, river discharge, upwelling and regional mixing processes. Over most of the western Arctic, and especially the Beaufort Sea, the concentrations of inorganic nitrogen (i.e. nitrate, nitrite and ammonia) at surface remain low throughout the year and the phytoplankton possibly depend on local recycling and the dissolved organic nitrogen (DON; e.g. urea, amino acids and primary amines) supplied by rivers. A large portion of the phytoplankton biomass is typically located within subsurface chlorophyll maxima (SCM). SCM productivity is possibly in balance with the episodic supply of nitrate across the halocline and/or the supply of ammonium and nitrate by local recycling and nitrification, respectively. Despite the importance of SCM for the food web and CO_2 fluxes, little is known about their structure, turnover and susceptibility to environmental variability and change.

Objectives. The main goals of our team for leg 7 of ArcticNet 2007&CFL were to **(1)** establish the horizontal and vertical distributions of phytoplankton nutrients and the influence of different processes (e.g. mixing, upwelling and biological processes) on these distributions, **(2)** characterize the detailed vertical structure of chlorophyll-*a* with respect to irradiance, nutrient supply and physical structure and **(3)** experimentally assess causal relationships between phytoplankton productivity and the availability of light.

Methods. Samples for inorganic nutrients (ammonium, nitrite, nitrate, orthophosphate and orthosilicic acid) and urea were taken at all rosette stations (see Table 1) to establish detailed vertical profiles. Ammonium was determined immediately after collection using modifications of the manual fluorometric method (e.g. Holmes et al. 1999). Urea samples were either frozen or analyzed fresh using the method of Mulveena & Savidge 1992. The concentrations of nitrate, nitrite, orthophosphate and orthosilicic acid were determined on fresh samples using an Autoanalyzer 3 (Bran+Luebbe) with colorimetric methods adapted from Grasshof (1999).

Samples for the natural abundance of ^{15}N and ^{13}C in particulate organic matter were taken from the ice-water interface, at 5 m and at 30 m (this last depth was chosen because there were no apparent maxima). Volumes ranging from 12 to 20 liters were filtered onto 47 mm pre-combusted GF/F filters with a peristaltic pump and the filters were desiccated at 60°C in a drying oven. These data will be used for nitrogen uptake calculations and to assess the nitrogen status of phytoplankton communities.

Nutrients and natural abundance samples were also taken from the bottom of the ice cores collected by C.J. Mundy and Benoit Philippe using the same techniques described above except that the volume filtered for natural abundance was 25 mL of ice core diltuted (100 mL of filtered seawater from 10 m was added for each centimeter of ice core to avoid osmotic shock during thawing).

Photosynthetic characteristics of phytoplankton taken from 3 depths (ice-water interface, 5 m and 30m) were assessed by Pulse Amplitude Modulated fluorometry (PAM; Heinz-Walz).

The Phytoflash system, powered by a CTD (SBE-19), was deployed in self-contained mode from the front deck at one station to obtain a baseline of the fluorescence quality in the water column. It was also deployed under ice during the dive program. The first one consisted in a vertical profile of 12 m and then the divers put the phytoflash against the bottom the ice. After uploading and verifying the data, the method was changed to try to obtain usable data. The phytoflash was then passed into a mist of floating ice algae created by one of the divers scraping the bottom of the ice with his hand.

Table 1. List of sampling stations and measurements during leg 7 of ArcticNet 2007&CFL.

Station	Cast	Date	Nuts Water Column	Nuts Ice Core	PAM	Natural Abundance	Phytoflash

2.6.2. Marine Microbiology Group

Participants: Dan Nguyen, Maranger team- Université de Montréal, Lisa Delaney, Lovejoy team - Université Laval

Introduction

Microorganisms are a heterogeneous group that include representatives of the three kingdoms of live, Archaea, Bacteria and Eukarya. Because of this heterogeneity these organisms accomplish key biogeochemical processes in the ecosystem. Autotrophic microorganisms are the base of the Arctic ocean trophic web, which comprises 7 orders of size magnitude, from the smallest cell, less than 1 µm microorganisms, to the largest mammals on the order of meters. All these organisms are strongly influenced by the lack of light during part of the year, the low temperatures and the ice cover. Comparing the species composition and activities of microbial communities in systems with diverse chemical and physical regimes is a good way to learn more about the importance of the different forces that determine how microbes use organic and inorganic matter and how this influences other components of the food web. This knowledge is needed to better predict the consequences of natural or anthropogenic changes on these trophic dynamics. This will also help us to evaluate the system's ability to buffer these changes at short and long timescales.

Objectives

Our group had an ambitious sampling program to be completed during this leg. The different protocols done though this leg covered the work of 4 teams: Corina Brussard, Connie Lovejoy, Roxane Maranger and Carles Pedrós-Alió. These protocols addressed different aspects of the microbial world, with the objective of giving a detailed view of the microbial diversity and processes occurring during the winter season.

During leg 7, we intensified measures of microbial respiration and began carbon consumption measurement in sea-ice. Our focus was to see how snow cover could affect these processes. For these measures, we used fiber optic O2 sensing (FIBOX) and regrowth experiment to determine consumption and lability of C.

We also wanted to monitor interannual variability and microbial diversity and relative abundance throughout the water column in the Amundsen Gulf. In order to do this, DNA and RNA was collected at various sites across the Amundsen Gulf and analyzed in Quebec City. A subset of this was to observe the variations in gene expression over seasonal time scales. Bacteria and archaea was the focus of this work. To compliment this data, pigments were recorded at the same depths as DNA and RNA.

The data recorded in this region will be compared similar data from previous years across the Canadian arctic.

Sampling

The sampling for this leg took place at the south and southwest off the coast of Banks Island. The comparison of samples gathered during the different wintering legs will allow a better understanding of the seasonal dynamic and the comparison of the different geographical areas will provide valuable information on the diversity and depth distributions of microbes.

Since the beginning of leg 7, we sampled at 6 stations (D29, D33, D35, D36, D38, D41). The sampling dates and the localization of the stations can be found on Annex 1. Our strategy was to obtain microbiological data from specific water masses through the water column with a special focus on the nutricline, the upper mixed layer, and the deep waters. These water masses were identified during the downcast of the CTD, based on the readouts from the temperature, salinity, oxygen, nitrate, fluorescence, transmissometer and pH probes.

When possible, surface water from about 2 metres depth was collected through holes in the ice. These samples will be compared to the 12 meters surface water collected from the moon pool inside the ship.

Variables Sampled

A table summarizing the samples obtained during leg 7 can be found on Annex 2 and 3. A brief description of the protocols follows.

1. Molecular genetics

a. DNA sampling. Samples for DNA were collected on every station at 4 different depths. During DNA collection water was prefiltered through a 50 µm mesh, excluding larger organisms to be collected. Water was then filtered through a 3 µm polycarbonate filter and the same water was again filtered through a 0.2 m filter. This sampling protocol gives two different samples, one containing the DNA from 50 µm to 3 µm fraction (Large fraction) and one containing the 3 µm to 0.2 µm fraction (Small fraction). After collection samples are keeped at -80 ºC until processing in the Lovejoy laboratory in Université Laval. These samples will give valuable information on the biodiversity and distribution of microorganisms.

2. Gene expression

Samples for RNA were collected on every station at 4 different depths. During RNA collection water was prefiltered through a 50 µm mesh, excluding larger organisms to be collected. Water was then filtered through a 3 µm polycarbonate filter and the same water was again filtered through a 0.2 m filter. This sampling protocol gives two different samples, one containing the RNA from 50 µm to 3 µm fraction (Large fraction) and one containing the 3 µm to 0.2 µm fraction (Small fraction). After

collection samples are keeped at -80 ºC until processing in the Lovejoy laboratory in Université Laval. These samples will give valuable information on the spatial expression of key genes.

3. Chlorophyll concentration

Samples for chlorophyll analysis were taken on each station at six or seven different depths. For each sample, one liter of water was filtered through a Whatman GF/F filter. This was the so-called large fraction, comprising all microorganisms larger than the nominal pore aize of 0.7 In addition, water was prefiltered through a 3 µm pore filter to obtain the small fraction, which was finally filtered through a Whatman GF/F filter. Afer filtration, the filters were stored overnight at -20ºC. Subsequently, the filters were introduced in acetone 90% and placed in a refrigerator, in the dark. After 24 hours, the fluorescence of the extracts, before and after acidification with 3 drops of 5% HCl, was determined by means of a Turner TD-700 fluorometer.

4. HPLC

Samples for High Performance Liquid Chromatography (HPLC) analysis were taken on each station at six different depths. Two fractions were collected, one for the total fraction (down to 0.7 µm) and one for the small fraction (from 3 µm to 0.7 µm). Samples were stored at -80 ºC and will be analyzed at Laval University.

5. Virus

Different variables associated with viruses have been collected.

a. Viral abundance.

b. Viral diversity

2 litters of surface seawater were concentrated on 50 mL using a Vivaflow system (30 kd cartridge). This concentrate will be used to analyze the diversity of viruses present in the surface seawater.

6. Organic matter

Using pre-combusted GF/F filters (47 mm diameter) in a passive filtration system (by gravity) samples for dissolved organic carbon (DOC), total organic carbon (TOC), amino acids and carbohydrates were taken. Samples without filtration for total phosphorus determination were also collected.

7. Bacteria and Archaea abundance

Microscope preparations for bacterial abundance estimations were prepared by filtering a small volume of water (20ml) fixed with formaldehyde and staining with DAPI (which bounds to the DNA). Microscopy slides were prepared on all stations at 6 different depths. Slides were frozen (-20°C) until counting on a microscope.

Bacterial preparations were also obtained in some stations using glutaraldehyde instead of formaldehyde as the fixative. These slides were frozen at -20 ºC until counting.

8. Ciliates

Samples for ciliates abundance and diversity were collected and preserved using a Lugol acid solution. These samples will be analyzed off the ship.

9. FISH: eukaryotes

The Fluorescent In Situ Hybridization is a powerful technique to study specific groups of microorganisms. Samples for FISH were collected on all stations at 6 different depths. Samples were stored at -80 ºC until analysis off the ship.

10. CARD – FISH: bacteria and archaea

Samples for the abundance and distribution of specific groups of prokaryotic microbes were collected in all stations at 6 different depths. These samples have been frozen at -20 ºC until its analysis with different oligonucleotide probes off the ship.

11. MarFISH: bacteria and archaea

Incubations with 3H-labeled leucine and C14-labeled bicarbonate were carried out to detect active prokaryotes in the uptake of these substrates at all sampled stations at a minimum of two depths (surface and base of the nitrocline). Leucine incubations lasted for 8 hours and bicarbonate incubations lasted for 24h always in the dark. After fixation of the samples, they were filtered and the filters were stored at –80 to be analyzed off the ship. In combination with the FISH technique this can give information on the phylogenetic identity of these active microorganisms.

Beside the MarFISH incubations, samples were incubated with C14-labeled bicarbonate (at a lower concentration) to measure bulk bicarbonate uptake by bacteria and archaea in the dark. These samples were incubated for 24 hours and subsequently filtered. The filters were exposed to HCl fumes overnight, and embedded in cocktail for the scintillation counter measurement.

12. Bacterivory – FLBs grazing

In order to acquire values of ingestion rates of bacteria by heterotrophic eukaryotes, Fluorescent Labelled Bacteria (FLB) obtained from a culture of *Brevundimonas diminuta* were used on bacterial grazing experiments. Three replicates and a 0.2 µm seawater filtered control with 10^5 cells/ml added were used. Samples for flagellates and bacterial microscopy observation and for bacterial production were collected at the beginning and after 48 hours of incubation at seawater temperature (cold-room). This experiment was conducted twice during the leg.

13. Alguivory – Micromonas grazing

Two grazing experiments with the *Micromonas* strain RCC497 were performed in order to calculate an ingestion rate of *Micromonas* cells by heterotrophic flagellates. For each experiment, two replicates of 2000 ml seawater filtered by 200 µm were incubated during 96 hours, at surface seawater temperature (-1.4 ºC). A control of 0.2 µm filtered seawater was run in the same conditions at the same time. Samples for FISH (to observe *Micromonas* ingestion) and flow cytometry (to observe *Micromonas* disappearance) were taken.

14. Bacterial production

Bacterial production rates were measured at six depths for each station using the leucine incorporation method (^{3}H labelled leucine) with 4 hours of incubation in coolers filled with ice-cold seawater in the radioactive lab. Samples were taken at every station at six depths, and also from surface waters below the ice. Rates of incorporation of radio labelled leucine were measured using the scintillation counter onboard.

17. Respiration

Bacterial/community respiration rates were measured using the FIBOX, which measures O_2 depletion in time using sensors glued to the bottom of 500ml Erlenmeyers. The consumption of O2 in time can

be converted in CO2 production to compare carbon respiration rate to bacterial carbon production rates. Each experiment lasted for about 15 days and oxygen measurements were made every 1-2 days. The Erlenmeyer were kept in the dark inside a cooler in a cold room. We intensified the number of experiment during leg 7, started measurements in melted ice and were running respiration measurements at full capacity (36 erlenmeyers simultaneously). We were able to measure respiration rates in melted sea ice and during the regrowth experiment.

18. ETS

Due to the low respiration rates in Arctic waters, a back-up method was also employed to obtain respiration rate surrogates via ETS (Electron transport system activity). This is achieved by filtering a large quantity (8L-10L) of water on GF/F filters to collect live cells and freeze them (-80°C) as quick as possible. Once off the ship, filters will be defrozen and the living cells will be subject to various enzymatic tests to measure activity.

19. N2O in the upper water column

N_2O Dissolved N2O measurements were carried out using the headspace equilibration method with 1.1 L of seawater. 3 samples were taken from 3 depths and will be analyzed off the ship for N2O on an electron capture detector (GC).

20. Carbon lability and consumption

To measure these variables we carried out two regrowth experiments. One of them will be passed to the leg 8 team. These experiment work on the principle of re-inoculation of a natural bacterial community (ice-water interface) in filter sterilized (0,2um) water or melted ice samples. To make sure that bacteria would only be limited by C, we added NaNO3 and NaPO4 to insure a minimal growth medium. Each 48h, we took samples for DOC analyses in Montreal, and each 4 day samples for flow cytometry to determine bacterial abundance. We hope that the DOC sample will gives more information on the lability of the carbon contained in the ice. Bacterial production was measured at the beginning and end of the experiments. These incubation were joined to respiration measurements using the same samples to see if DOC could sustain bacterial processes over a period of time (15-20 days).

Other activities

The team participated in all social activities of the ship. Lisa gave a few interviews to media members. Dan wrote a dispatch to be published on the CFL webpage. We helped other teams on the digging of holes in the ice and ice core sampling. We also provided 0.7 µm filtered seawater for the zooplancton team.

Note:

Lisa Delaney had to leave for the last week of the leg to help schools on board actually getting on board. We were still able to complete normal sampling activities without major compromises.

Acknowledgements

We would like to thank our Chief Scientists (Tim Paparyakou and Dave Barber), Captain Louise Marchand and crew of the Amundsen for the excellent work done during leg 7. Thanks to CJ Mundy, Benoit Philippe, Chantal Lacoste, Maike Kramer, Tom Brown and Rodd Laing for there help collecting the ice cores on those cold arctic days and to Yves Gratton for his help and advice on the rosette.

2.7. Team 8

PI: Gary Stern (DFO, Freshwater Institute)
Participants: Debbie Armstrong (University of Manitoba), Alexis Burt (MSc student, University of Manitoba), Alex Hare (PhD student, University of Manitoba), Monika Pucko (PhD student, University of Manitoba), Sandy Steffen (Environment Canada, Toronto), Crispin Halsall (Lancaster University, UK), Sabino del Vento (Lancaster University, UK)

General objective
This question this project hopes to answer is how climate variability in physical forcing and the biogeochemical response to this primary forcing will affect organic contaminants and mercury (Hg)/methyl mercury (MeHg) contaminant cycling. Ultimately, we propose to relate changes in delivery and biogeochemical cycling of these contaminants to their levels in fish, marine mammals and the people who consume these tissues as part of their traditional diets.

An additional sampling campaign was undertaken during CFL 2007-2008. The program is designed to obtain a detailed picture of PFOA (perfluorooctanoic acid) and PFOS (perfluorooctane sulfonic acid) concentrations in near shore and open ocean sites in the Canadian arctic.

2.7.1. Organic contaminants

Hexachlorocyclohexane (HCH) (Pucko)

Technical HCH is a mixture of several isomers, the most abundant being □-HCH (60-70%), □-HCH (5-12%) and □-HCH (10-15%). Technical HCH and pure □-HCH (lindane, pesticide active isomer) have been used for over 50 years and are now ubiquitous in water throughout the northern hemisphere with the highest levels found in the surface water layers near pack ice in the Arctic Ocean.

Technical HCH was banned or heavily restricted by China, the former Soviet Union and India between the mid-1980s and 1990. Concentrations of □-HCH in arctic air responded quickly to these large-scale usage changes and declined by an order of magnitude from the early 1980s to mid-1990s in steps that closely matched global usage and emission estimates. As a consequence, the direction of net gas exchange in arctic waters reversed from deposition in the 1980s to air-water equilibrium or volatilization in the mid-1990s.

The □-isomer is the prominent in Arctic air, water, biota and soil, and moves northward via cold-condensation, a process whereby the contaminant evades into the atmosphere, drifts with atmospheric currents, and condenses in colder climates where at colder temperatures increasingly favours the water and extensive ice cover inhibit further evasion. Hence the contaminant accumulates disproportionately in the Arctic.

HCH water sampling
Water (4L) was collected from the rosette every 4-6 days. Where feasible, transects across water bodies were collected. In the lab, water was pumped through a glass-fiber filter followed by an ENV+ solid-phase extraction (SPE) cartridge using peristaltic pumps. Filters and cartridges are frozen and brought back the Freshwater Institute for analysis. $^{18}\delta O$ were also collected at each site and depth where HCH samples were taken.

HCH air sampling

The air sampler was set up on the bow of the ship on the starboard side along with each ice sampling. Samples are collected on a glass fiber filter and polyurethane foam (PUF) for analysis of organic contaminants. Air samples collection time ranged between 4 and 10 hours. Filters and PUFs were frozen at -20°C and shipped frozen back to the FWI for HCH contaminant analysis.

HCH ice sampling

Ice samples for HCHs concentration and enantiomeric composition were collected. The samples for oxygen isotope composition ($\delta^{18}O$) and salinity were taken along with all ice samples. The ice samples were collected in collaboration with team 2 and the ice microstructure and physical analysis was made on all of them (see team 2 cruise report). Ice cores were cut according to ice microstructure into 15-40cm layers or the whole core was taken, melted (4-8L of water) and pumped through a glass-fiber filter followed by an ENV+ solid-phase extraction (SPE) cartridge using peristaltic pumps. Surface water (4L) and 5m water were sampled along with almost every ice sampling using a Niskin bottle. The cartridges and GFFs were stored in -80 □C and brought to the DFO (Winnipeg) for further chemical analysis.

HCH snow/frost flowers sampling

At some sites snow/frost flowers were sampled for HCH analysis. Air was always sampled along with the snow/frost flowers sampling. Where possible, snow was sampled in layers. Snow/frost flowers sampling for HCH analysis was mostly done in collaboration with team 2 snow pit sampling (snow density, salinity, temperature and grain characteristics were measured). Snow/frost flowers samples were taken with a metal pan into plastic bags. After melting, 8L of melt water was pumped through a glass-fiber filter followed by an ENV+ solid-phase extraction (SPE) cartridge using peristaltic pumps. The cartridges and GFFs were stored in -80 □C and brought to the DFO (Winnipeg) for further chemical analysis.

Bacterial experiment
Bacterial cultures from 9 different depths in the water column cultured by Marcela Ewert (Jody Deming's team) during leg 5 were maintained throughout leg 7 and will be taken back to Winnipeg for HCH EF degradation experiments.

The role of the Arctic in the global cycling of Persistent Organic Pollutants – ARCPOP
(Halsall, del Vento)

Overview
The purpose of the Halsall group's work is to examine the transfer of persistent organic pollutants (POPs) between the key Arctic compartments of air, snow, sea-ice and seawater during the period following polar sunrise (leg 7) to early summer (leg 8). Organic contaminants of interest include the 'legacy' POPs, such as the organochorine pesticides and polychlorinated biphenyls, as well as 'emerging' contaminants such as the perfluorinated alkylated substances (PFAS) and select current-use pesticides. The transfer and fate of these chemicals in the Arctic marine environment is poorly understood and yet their 'cycling' between air-seawater is likely to be strongly controlled by seasonal fluctuations in sea-ice cover. In addition, the role of snow in transferring airborne contaminants to marine surfaces with subsequent uptake to the marine foodweb is also an area for investigation.

Sampling strategy
Integrated sampling was conducted whenever possible; combining air, snow and seawater sampling at various CFL stations during leg 7. Due to the diversity of target analytes, separate sampling equipment and strategies where adopted. These were roughly distributed between 'large volume' techniques for legacy POPs, and 'low volume' sampling methods/techniques for PFAS.

Air samples
Leg 7a (Halsall) involved laboratory set-up (Benthic Laboratory – 400 deck) and the deployment of a high-volume (Hi-Vol) air sampler at CFL station 30. Initial 48 h samples were taken for 'legacy' POPs, with the sampler deployed on the ice, approximately 50 m both downwind of the ship, followed by sampling upwind of the ship. The dark colouration of the filters for the first two samples, (downwind of the ship) indicates that these were probably compromised by the ship's exhaust.

Hi-Vol air samples were subsequently collected throughout leg 7b to establish POP air concentrations, with samples collected both on the ice, upwind of the ship and on the roof of the top bridge. In addition, air samples using a modified Hi-Vol sample train comprising of a PUF/XAD vapour trap were taken for PFAS.

Figure 1. Hi-vol air sampler deployed on the ice at CFL station 31

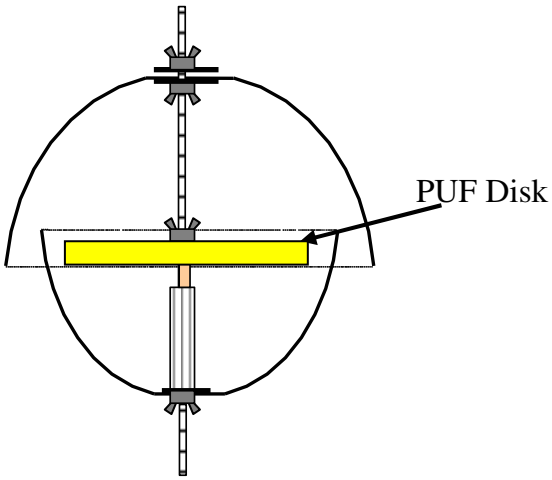
23-Apr-08	24-Apr-08	D42

Passive air samplers (PUF-disk samplers) (2) were deployed at the stern of the ship, close to the aft labs, as well as within the benthic laboratory (1) to assess ship-based contamination, particularly for polychlorinated biphenyls (PCBs) and polybrominated diphenyl ethers (PBDEs - flame retardants). Elevated levels of these compounds are typical of many marine research vessels and deployment of PUF-disk samplers will serve as a useful quality control for the contaminant group as a whole.

PUF-disk samplers were also deployed (3) on the meteorological mast at the bow of the ship at different heights and these may reflect true contaminant levels in the Arctic marine boundary layer, and will be compared to the aft samplers. One sampler fell off the tower due to strong wind gusts presumably on 5th April. It was replaced on 18th when the meteorological mast was down for some maintenance. Two PUF-disk samplers were placed on the top of bridge in proximity of the Hi-vol position on 22nd April.



Schematic of PUF Disk passive sampler

Seawater samples

The onboard (teflon-lined) seawater line was used to collect large volume seawater samples for POPs. Seawater was sampled from the well-mixed surface layer (~7 m depth) and passed through an in-line filter and XAD-cartridge system, which operationally collects the respective particle-bound and dissolved fractions of POPs Problems were encountered with the seawater-line; notably rust-like deposits present in the water as well as erratic flow rates from the pump/tap. This resulted in clogged filters and low sample volumes. Nonetheless, seawater samples comprising of volumes of <500L were collected and will be analysed fro OC pesticides and PBDEs, although these samples may be compromised due to the rust deposits.

Figure 2. Onboard seawater sampling line in the Benthic lab

Low-volume samples (2-4L) were collected from beneath the sea-ice at CFL stations 29-32-33-38-40-41 for PFAS, these will related to the Hi-Vol air samples to examine the transfer and chemistry of this class of contaminants between the air and marine surfaces.

Snow & ice samples

Three 50L gas-tight snow sampling cans were deployed at CFL station 31 (leg 7a) and 33 (leg 7b) and used to collect sea-ice snow samples

Figure 3. Snow-can meltwater extraction

Figure 4. Snow-cans deployed on the ice

Contaminant concentrations in snow will be related to snow physical properties as well as concentrations observed in air and underlying seawater. Snow-cans were also used to collect and melt sea-ice cores to examine contaminant levels in ice. Low volume (2-4 L) snowmelt and ice-core samples (36-38-40-41) were also taken for PFAS.

2.7.2. Mercury

Rationale

Mercury (Hg) levels in marine mammals and fish are an ongoing concern in Arctic regions because of their inclusion in traditional subsistence diets among indigenous peoples in northern regions. Successful strategies to mitigate health impacts related to Hg in human diets require an understanding of both the social and cultural perspective of northern communities, as well as the natural environmental processes that lead to Hg in food resources. Our research on Hg in the Arctic is focused on determining the environmental processes responsible for the distribution and speciation of Hg in Arctic marine ecosystems, for the purpose of supporting the development of strategies to lessen the impact of Hg on human and ecosystem health.

Water Column Sampling

During Leg 7 of the CFL Study, the Team 8: Contaminants group collected samples from the marine water column in Amundsen Gulf from eight locations along its northwestern border with Banks Island (Table 1). Samples from the 10 m depth to the seafloor were collected with the ship-based Rosette sampling equipment in PVC 'Niskin-style' sample bottles remotely operated from onboard the ship. Supplementary 'Surface' samples from 0 to 10 m in depth were collected by a PVC Niskin water sampling bottle (General Oceanics, Miami, Florida) from a hole or open lead within a few hundred meters of the ship and within three hours of the Rosette collection (Table 1). Within each profile, 11 to 20 different depths were sampled (including Niskin sampling), producing high resolution profiles for 'total Hg' (Hg_T). At each depth sampled for Hg_T, water was also collected for $\delta^{18}O$ analysis in tightly sealed glass scintillation vials. After collection of $\delta\ ^{18}O$ samples, bottles were further sealed with parafilm and stored at 4°C.

Sample Analysis

After collection of marine water for Hg_T analysis, samples were spiked with ultra-pure 0.5% HCl (JT Baker, Phillipsburg NJ) and 0.5% BrCl and stored at 4°C. Hg_T samples were subsequently analyzed by cold vapour atomic fluorescence spectrophotometry (CVAFS) within 48 hours of collection in the

Portable In Situ Laboratory for Mercury Speciation (PILMS) onboard the CCGS Amundsen. Analysis followed the guidelines of the US EPA Method 1631.

Preliminary Results

Hg_T levels in the Amundsen Gulf measured during Leg 7 were very low, averaging roughly 1 pM (0.2 ng/L) throughout the water column. These values are comparable with the lowest concentrations of Hg_T observed in the global oceans (e.g., the Pacific and North Atlantic Oceans), and somewhat lower than those observed in coastal oceans and regional seas (e.g., the Baltic and the Celtic Seas, Hudson Bay).

Table 9. Sampling Location and Date for Marine Water HgT Measurements During CFL Leg 7

Station	Date	Latitude	Longitude	Bottom Depth (m)	Number of Sample Depths
D33	March 24	71° 3.848	-121° 47.227	188	11
D33	March 27	71° 3.846	-121° 47.202	188	17
D33	April 1	71° 3.885	-121° 47.224	188	17

Atmospheric Mercury

Speciation System on the Ship:

This instrument has been working well for the time I have been on the ship. The data is shown in Figure 1. Table 1 indicates days when data was collected. Table 2 indicates dates when atmospheric mercury depletion events were recorded.

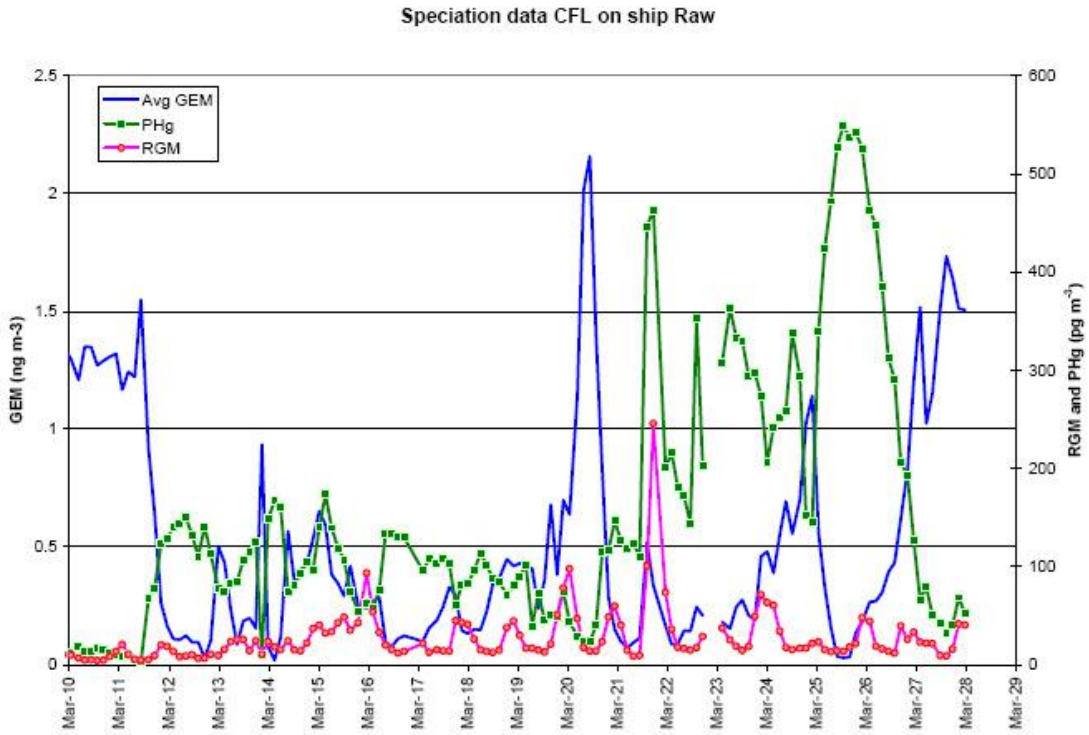
1. Glassware was changed on March 22 and April 16.
2. Injections were done on SN 323 on April 16 – nothing was changed they all looked reasonable.
3. I did not see that any standard additions were made on this instrument before I got here. Once a week I have been manually hooking up the SAU (standard addition unit) to the speciation system to run standard additions to check how well the cartridges and the instrument are working. For the most part they are ~130% recovery but that high recovery may be a reflection of the pressure from the setup when taking the sample. The SAUs have been consistent throughout my stay here so that is considered good. These weekly SAUs on the system should be kept up on the next leg in order to maintain track of the quality of the data set. Without these SAUs we lose ability to really QC the data well.
4. The flow of the speciation system is set to 9 lpm. When I arrived, the flow was about 8.6 and the pump was working hard. After a glassware change the pump worsened and so I took out some of the quartz wool from the RPF. Debbie and I adjusted the back pressure regulator so that a flow of 9 lpm was recorded. However, as time went on the flow went back to approximately 8.6. This is an issue for 2 reasons 1) the particle cutoff for the instrument (0.25□m) occurs with the impactor when the total flow is 10 lpm (9 from the pump and 1 from the Tekran 2537. If the flow is not 10 then we are getting differently sized particles than what we expect in the system; 2) the concentration is calculated from the instrument as if the flow was 10 lpm but if its not, then the concentration that is reported from the instrument is not correct. Over 2 hours with a total flow of 9.6 lpm we have a difference of 48 litres of air going through the system. This thus must be recorded in the daily log as to the average flow of the pump unit so that we can make a decision on how to deal with the data at a later date. Note: after glassware was changed on April 16 the flow went to ~9.2 lpm.

5. There seem to be denuders missing. Debbie and I can only account for 4 denuders in total between the 2 speciation system. Of those 4 denuders 1 is broken in Winnipeg and 1 is cracked at the threading at the top. Patrick is sending 2 more denuders with Fei but we must establish how many denuders were sent up, how many have been broken and to whom to the existing denuders belong. A retort stand would be useful in the lab for coating denuders. Jeff may wish to bring one up with him when he comes.
6. Time setting. I have been making sure that the speciation system and the pyrolysis system are on the same time (within about 15 seconds of each other). This time is set with Tim's data logger so that we can relate the time back to the met data from Tim and the ozone data from Ralf.
7. Naming of files. Patrick has named the files and referred to the 2537 for the speciation system as 85 which is the serial number of the pump unit. I started naming things according to its correct serial number on March 16.
8. This crew has been very respectful of the BR being on and when they run it, they tell us so that we can record it or if the BR needs to be running all day they have put it on the ice. Please make this arrangement with the new crew that comes in. It should not be on as much as the weather is getting warmer but they will still have it on and this WILL affect the PHg data!
9. Soda lime trap change: it is evident in the data when the soda lime trap must be changed. You will see it in the GEM data throughout the cycle. At the beginning of the cycle it will be low and then as the 2 hours continues it reaches normal ambient concentrations. When you see this pattern show up the soda lime trap needs to be changed.
10. Sending data to Sandy. I would like if you can send the data on a daily basis to me in Toronto. As I have mentioned we need to ramp up surface water and snow sampling when we see the switch from PHg to RGM predominance. I am willing to keep a close eye on the data if you will just e-mail me the raw data files - I will put it together and send if back to you. You will download the data on a daily basis anyway so if you can just e-mail it as well that would be great.

Pyrolysis or Total Atmospheric Mercury Measurements:
Initially this system was running on 2 instruments SN 170 (ambient – total gaseous mercury (TGM)) and SN 51 (heated/pyrolysed- total atmospheric mercury (TAM)) air. On March 27 SN 170 stopped functioning and was not repairable on the ship. This instrument was having similar problems on Leg 6 but managed to fix itself, but that was not the case on Leg 7. It was packed up and a switching box was installed on SN 51. The 2 inlets are installed into the switch box and the box uses a solenoid to switch from one inlet line to the other every 3 samples. This took a week to install and get functioning properly due to contamination problems in the sample lines and subsequently the instrument. The dates when data is collected with this system are shown in Table 1. The Flags for this data are as follows:
FLAG 0 – ambient air (TGM)
FLAG 2 – heated air (TAM)
FLAG 1 or 3 – standard addition
FLAG 5 or 7 – zero
Note:
a) when 2 flags fall on the same sample the system adds the numbers on the flags
b) because the switching valve is at the end of the sample lines, the air that is in the lines when not sampled is stagnant and thus the first sample after a switch is not valid

NOTE: when the power is shut off on SN51 the date resets itself to 2014. Please follow the directions on the post it note stuck to the instrument when this happens to reset the TIME/DATE and the NEXT autocal settings.

Figure 1: Speciation data for on-ship measurements



Speciation on the Ice:

Debbie and Sandy had a box constructed to house the 2537 and the 1130 pump unit, in order to operate this system on the ice. A stand was built to house the 1130/35 system on the ice so that the inlet is about 6 inches form the snow surface. The purpose of collecting this information is to try and understand whether the actual atmospheric chemistry for AMDEs occurs immediately at the snow surface or further up in the boundary layer. Further, it is desired to assess if the distribution of the species RGM and PHg differ at the lower level close to the ice than up higher from the ship. Organising this instrumentation took longer than anticipated and was only deployed on the ice for the first time on April 1st. The instrument setup is illustrated in Figures 2 and 3.

Figure 2: speciation system

Figure 3: pump and atomic fluorescence instrument

There were a few more issues to deal with in order to get the system running (freezing of lines, freezing of solenoid valves, power to the system and the lack of a controller unit etc). Data was collected manually (via hand controller) between April 1st and April 3rd when the controller arrived. We got 1 night of data with the controller unit and the system was operating well. On April 4th the ice broke up and the equipment was removed from the ice. Up to this time the system was operating on ship power via a power cord from the port bow of the ship. The system was redeployed to the ice on April 12 using a gas generator. The system was installed on the port bow side of the boat. The system ran using this set up from the 12th to the 13th of April and then was removed from the ice because of ice break up. The system was redeployed to the ice on the 16th of April and was left on the ice until the change of Leg 7. Preliminary data is shown below in Figure 4.

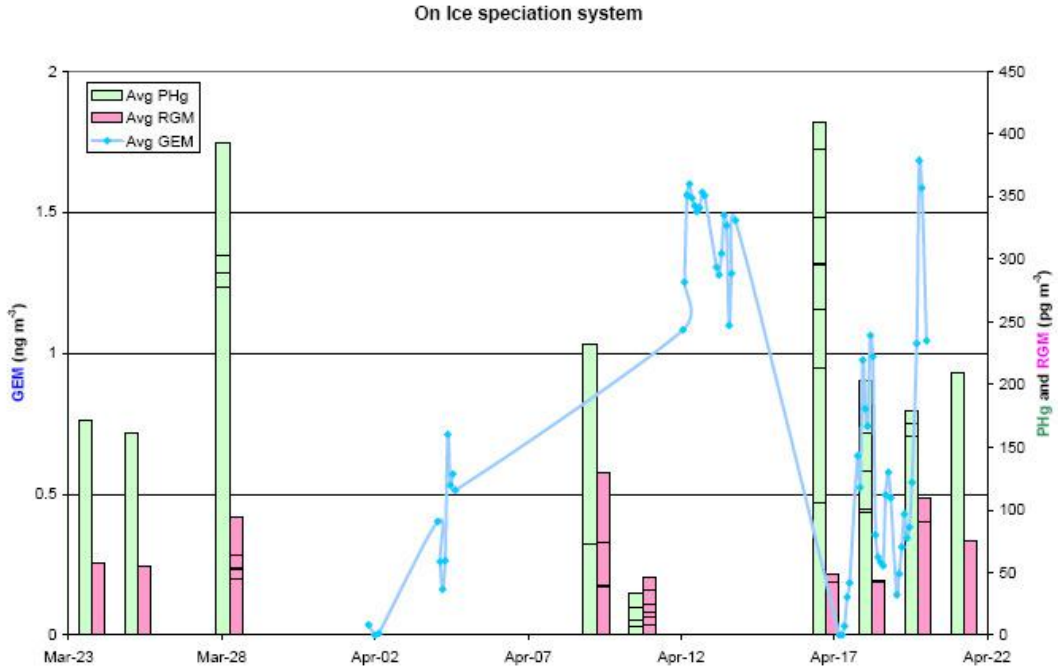


Figure 4: Speciation data for on-ice system

Ozone (TECO):
The ozone analyser (OASIS) will continue to be run throughout the Hg campaign. It is located in the OASIS shed by the bridge. This system will be checked daily along with the Max-DOAS measuring BrO from the person in charge of the Hg air program. Details for these checks have been left on the ship and will be in the handover notes.

Table 1: Dates of preliminarily valid data

Atmospheric species	Instrument	Dates collected
GEM	SN 323	March 14 to April 24
PHg	SN 323	March 14 to April 24
RGM	SN 323	March 14 to April 24
TGM (CRPU)	SN 51	
TAM (CRPU)	SN 170	March 14 to March 26
	SN 51	March 14 to March 26
	Switch box on SN51	April 13 to April 24
GEM (ice surface)	SN 71	April 1-4, 12-13, 16-24
RGM (ice surface)	SN 71	April 1-4, 12-13, 16-24
PHg (ice surface)	SN 71	April 1-4, 12-13, 16-24

Table 2: Dates of Atmospheric Mercury Depletion Events

Depletion No on Leg 7	Depletion Event Start	Depletion Event End
1	March 11	March 20
2	March 20	March 25
3	March 25	March 27
4	March 31	April 5
5	April 10	April 11
6	April 15	…

Dissolved Gaseous Mercury – DGM

A system has been developed to measure dissolved gaseous mercury (DGM) in surface waters collected from either a niskin or the sea water sample line which has been installed directly into the PILMS laboratory. The system uses a specially designed vessel in which mercury free air generated by a zero air generator is bubbled through the sample and then measured by a Tekran 2537B unit. The zero air is purged through the vessel for 50 minutes in order to recover a high portion of the DGM in the 1 liter of sample water.

Mercury in Ice, Brine an d Snow

In order to study the cycling of Mercury in the Arctic environment, we need to understand how it moves through the barrier separating the atmosphere and ocean known as ice. Movement through ice is thought to be carried through the network of brine channels that are formed within the ice and the interaction of that brine with the water column with the onset of spring. Another important factor to

consider is the impact of snow or deposition as a source from the atmosphere to the snowpack, ice column and directly into the ocean.

On leg 7 we collected ice cores, snow samples and brine samples at varying depths in order to track the movement of mercury with these media. Samples of each were collected over varying time series at stations: D29B, D33 (thick) and D33 (thin), Land Fast Ice Camp Site, D36 (new ice, thin ice and thick ice), D38, D41 duplicate cores. All ice cores were cut according to ice microstructure and cut into duplicates. Each duplicate was scrapped with a freshly cleaned and tested ceramic blade. Both pieces were placed into separate zip lock bags and then stored in one larger bag to melt. When sampling, each individual zip lock bag was rinsed with MQ water over the area that would be cut and then sampled. A small amount was rinsed out and then the sample was collected. For example, a 5 cm piece of ice split would yield two 25 mL samples of water in the end.
The scrapping was very clean, and the gloves were changed between each section of the core to be scrapped. This is essential to good reproducible results.

Snow samples were collected on a daily basis but need to be run at a 10x dilution or they are too high. We sampled one 30 cm snow pit was sampled at every 5 cm at Station D33 and I encourage others to continue this for leg 8.

The Hg profiles in brine are very interesting and brine holes at the depths of 40 cm, 60 cm, 80 cm, and 100 cm were sampled as a time series event. The results are quite exciting and this work should continue as long as possible. As the temperatures increase with the season the amount of brine produced increases and the mercury levels vary consistently between depths. Salinity was measured on all brine samples in the airlock of PILMS (CEOS probe). Salinity of the holes even after being fully drained, remains the same, as do the mercury levels. Sampling frequency was once in the evening after the holes had been drilled then everyday thereafter. Brine samples have been diluted 5x before running on the tekran.

Methyl Mercury

The form of mercury that accumulates within the foodweb is the organic form of mercury known as methyl mercury. We are interested in determining the pathways in which mercury (Hg) becomes methylated and to study the levels in the abiotic and biotic environments. The instrument is not stable when the ship is moving and the system seems to give us varying results but we are determined to have a ship based program up and running soon. This is the first time this technology has been used on a ship of this size and in ice breaking conditions which seems to pose some vibration problems.

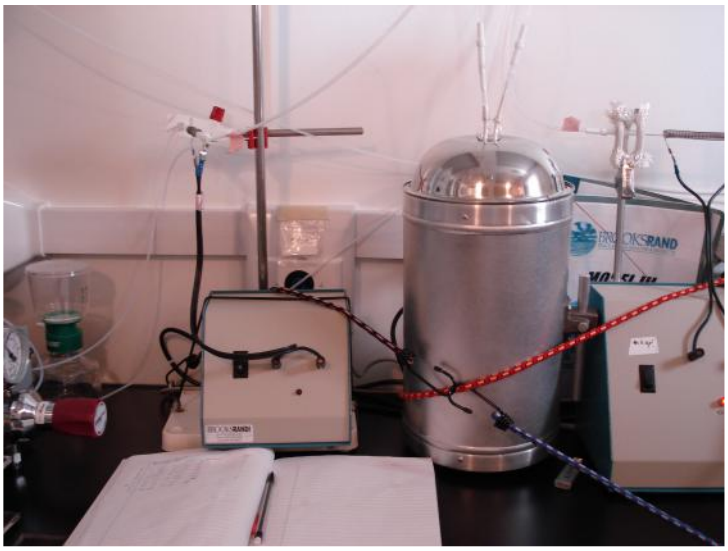

Figure 1: Trap and column to separate the organic mercury species

We found that the sensitivity of the instrument was quite low although our reagents were working well. It was also determined that the traps needed to be heated before use to avoid extra unknown peaks. It is essential that they be burned off the day before use. The lamp was changed in the detector and the gas pressure was set to 10 psi on the small regulator to ensure proper peak separation on the GC column. We have produced some results but it is not easy to maintain the sensitivity.

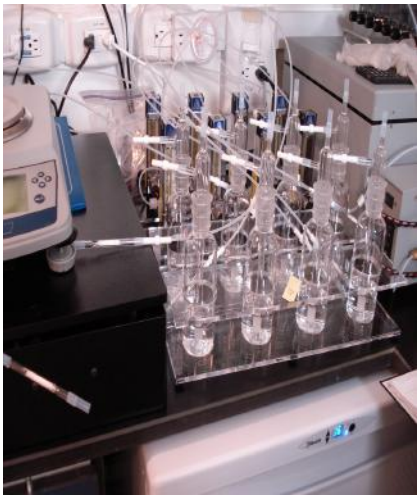

Figure 2: Purge and trap module to trap the organic species of mercury

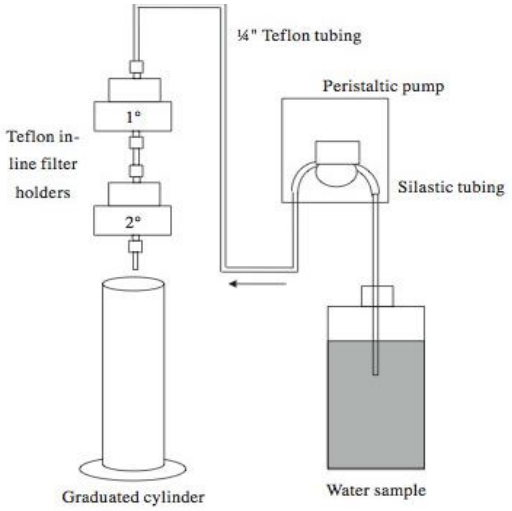
2.7.3. Biotic sampling (HCH, Hg, MeHg, Stable Isotopes, Fatty Acids)

The main purpose of this study is to link physical and biological processes to mercury/HCH levels in the food web and to target the pelagic food web biomagnification and bioaccumulation of HCH and mercury with stable isotopes and fatty acids. Thus, all biological samples collected will be measured for HCHs, total mercury and MeHg along with stable isotopes to place organisms into their associated trophic levels.

Algae (HCH)
At stations D38 and D41 ice and under ice algae were sampled for HCH analysis. Samples were taken by divers from under the ice with a slurp gun (under ice algae community) and ice scraper (bottom ice algae community). Subsequently, they were filtered through the GFF filters, frozen and taken back to Winnipeg for further analysis.

Algae (Hg, MeHg)
Phytoplankton samples were taken in conjunction with zooplankton tows. Samples were sieved through 710µm, 350µm, 50µm and 20µm mesh and frozen. Samples were also preserved with lugol's for speciation.
Phytoplankton was collected at stations D36 (x7), D38 (x3), D40 (x3), D41 (x6).
Surface water phytoplankton was collected with a clean niskin bottle, from the ice-water interface with a battery powered pump on a metre long under ice arm, and collected with a slurp gun from the ice-water interface during the dive program. These samples were filtered onto pre-combusted and weighed glass fibre filters (GF/F) for chlorophyll a, dry mass, and filtered in series with a clean set up for mercury, with a blank (see figure). The filters were frozen, and will be shipped to Winnipeg for further analysis.



Filtration set up for algal Hg (exception: the peristaltic pump is between the filters and the waste container)

Surface water algae was collected at stations D29, D33 (x2), D36, D38 (x2), D41 (x2).
Ice algae was collected by coring, and also during the dive program via an ice scraping contraption. An ammount was preserved for speciation, while the buk was frozen for shipping.
Ice algae was collected at stations D29 (x2), D31, D34, D33, D38, D41 (x2).

Alex Hare and Alexis Burt coring

Zooplankton

Zooplankton samples were collected on a daily basis. Various zooplankton families were collected using the vertically towed Tucker net (mesh size 0.2 mm) from the moon pool, and vertical, horizontal, and oblique tows from the ice using a double tucker net (200µm mesh). To obtain the species specifically grazing under the ice (e.g. *Calanus glacialis* AF) vertical tows 0-60m were done from the ice with a 200µm Ring net. Zooplankton was sorted into families,, or to genus and species where possible, placed in plastic vials and Whirlpak bags and frozen until they can be analyzed for HCH, THg, MeHg, stable isotopes and fatty acids. Common species found were *Calanus hyperboreus*, *Calanus glacialis,* Paraeuchaeta *glacialis*, *Sagitta elegans, Sagitta maxima*, *Themisto abyssorum*, *Themisto libellula, Metridia longa, Ostracoda* sp., Cnidarians, Ctenophores, and Polychaetes. Some less common species found were *Cleone limacina*, *Gaidius* sp., *Hyperoche* sp., Euphasiids, *Pandalus* sp., and one *Liparis* sp. (a bottom feeding fish). Zooplankton was collected at stations D29 (x 3), D33 (x12), D36 (x 3), D38 (x2), D40, D41 (x4) for a total of 24 zooplankton hauls.

Double Tucker Net (horizontal and oblique tows on the ice)

Special thanks to Gerald Darnis, Luc Michaud, and Catherine Lalande for their patience and expertise on all things related to zooplankton.
Thanks to Tim Papakyriakou for the use of equipment in the field, and always caring how the day is going.
Thanks to Alex for encouragement and tips.
Thanks to the crew for always being there. 24-7.

Leg 8

25 April – 5 June 2008

edited and compiled by Michel Gosselin, Jean-Éric Tremblay and David Barber
(Chief Scientists)

1. General overview

1.1. Introduction

Leg 8 of the CFL project was succefully completed on June 5. The science plan allowed for several drift stations in Amundsen, a transit north to McClure Strait and sampling across the flaw lead just west of Banks Island. The ship also visited the multiyear pack ice at the north end of our sampling area. Towards the end of the period we established a late season fast ice site in Darnley Bay. The chief scientist duties were shared by Michel Gosselin (8A), Jean-Eric Tremblay (first 2 weeks of 8B) and David Barber (last week of 7B). A summary of these three periods are as follows:

Leg 8A (Michel Gosselin)
On 24 April, the charter flight left Quebec City on time at 2:00 AM and landed in Winnipeg to get other science personnel. The plane arrived in Inuvik at 10:00 AM. The exchange of personnel went smoothly, all the science and Coast Guard personnel was on board the ship at 7:30 PM. A landing strip was made on the pack ice close to the ship. The ship was located at the drifting station D43 on the eastern side of the 1000 transect line of Amundsen Gulf.

On 25 April, the science personnel located their materials and equipment and organized their laboratories, assisted to the ship familiarization and participated to 2 science meetings. During Leg 8A, science meetings occurred every night at 7:00 or 8:00 PM. There were 5 steering committee meetings during this leg to discuss the expedition plan and the sampling strategy.

The sampling started on 26 April at Sta D43. From 24 April to 5 May, the ship drifted 100 n.m. westward along the 1000 transect line. Before leaving this station, a beacon was left at this station, in case of further need of the landing strip. On 6 May, we sampled an open water station (1020A) west of Sta D43. On 7 May, we transited to Cape Parry and encounted heavy ice conditions along our route. At 7:30 PM, the ship was parked in the landfast ice of Cape Parry (water depth: 55 m). On 8 May, a Twin Otter landed at Cape Parry for the exchange of the 2 media persons and to conduct the aerial beluga survey on the west coast of Banks Island. The landfast ice station of Cape Parry (Sta F1) was sampled on 8 and 9 May.

On 10 May, we left Cape Parry for Franklin Bay. We sampled at two open water stations along the ice edge (Stas O1 and O2) during our voyage to the overwintering site of CASES in Franklin Bay. From 12 to 15 May, we worked at the landfast ice of Sta F2. This station was close to Sta 1116, the overwintering site of CASES. The ice edge was located around 2.5 n.m. north of Sta. F2. A landing strip was made on the landfast ice in preparation for the mid-leg crew change.

Leg 8b (Jean-Éric Tremblay)

Fifteen people (including JET, 12 scientists and 2 artists) arrived onboard in early afternoon after uneventful flights. The flight plan was modified slightly because there was no fuel left in Paulatuk and the weather (freezing rain) did not allow the beluga survey to proceed. Ten scientists and 2 media disembarked and flew back to Innuvik. Sampling activities continued on the 3-day cycle. In the evening of the 15th the wire of the scamp caught into the port side of the moonpool opening, presumably in a dent that we can't see. The instrument was recovered only in the morning with a long gaffe. Some of the wire was lost, but there was no damage to the instrument. During the time the ship was operating in Franklin Bay, easterly and north-easterly winds pushed drifting ice floes against the fast ice, creating a pressure ridge along the whole longitudinal swath of the bay. For a while it looked like the ship was going to be trapped, but an ice patrol on Saturday 17 May confirmed that we could leave the bay via the eastern side. The beluga survey proceeded in the afternoon; the plane arrived at around 14h00, took off at 16h30 and came back at ca. 22h00.

We continued on the regular sampling cycle (same as drift mode) until Sunday morning at 9h30, at which time the ship broke off and sailed into the open waters of the Gulf of Amundsen. An e-mail was sent to Joane Eldridge to inform the HTC of our plans for the next few days. On 19 May, we began a full station 2 miles off the mooring site (CA18-07, or 405) which we called 405b. There was some concern expressed by the captain that Rosette operations were sometimes difficult because the rosette wire cannot always be seen beneath the cable guide in productive waters. This led to an e-mail exchange between Steve, Luc and I. The decision was made to continue rosette operations in the moonpool since many ice stations were planned for the future. Work proceeded swiftly and we left 405b on schedule, sailing north to go into the entrance to Prince-of-Whales Strait. The ship stopped in the ice at around 06h00. The station (F-3) was in the middle of the strait, at the southern margin of the fast ice. We opened the moonpool, which was clear of ice but unfortunately the ship moved a little and it filled up with ice. With the other operations being underway (ice raids), it took nearly 4 hours before the moonpool could be emptied with the cage and so the station finished at 02h00 with moonpool operations (the physics team sampled over one spring tidal cycle - 13 h). Meanwhile white-out conditions prevented the helicopter from retrieving the fuel drums and all the flights planned for John Iacozza and Randy Scharien were cancelled. Later in the evening a successful snowmobile expedition led by René (with 3 crew members and Roger) recovered the drums.

The ship left the station soon after 02h00 on 20 May and sailed for the edge of the drifting ice in the Gulf of Amundsen. We stopped at a location (70°43.76′N; 123°59.92′W) mid-way between stations 1010 and 1012 along the 1000 line, where a 1.7 mile wide ice floe had been spotted on the latest Radarsat image. We called this station 1011. The station was picked to contrast the conditions sampled in the open Gulf two days earlier (405b) with the situation in the retreating pack of drifting ice floes. The ice raid begun at 14h30 on 20 May and open water operations followed until 00h30. We spent the night in an ice flow and finished operations in the morning.

On 21 May we sailed to the northwest, crossing the pack of drifting ice floes to reach the open waters of the flaw lead west of Banks Island. A message was sent to Joane Eldridge to that effect. It took three helicopter patrols during the day to guide the ship across the floes. Nathalie Asselin came on all flights to record beluga sighthings (one large pod and several individuals were sighted, which proved very useful for her work). We reached the open water in the evening of May 21st and parked in a floe for the night. In the morning of the 22nd we positioned the ship at station 1806 and began a full station there. During that time the barge was tested as it was our intended means of deployment for sampling in the land-fast ice near the coast. The visibility was very poor (fog) and the EM flight planned for John Iacozza over the fast ice was postponed. Operations finished at 20h00. The ship moved closer to the coast into 30-m deep water on a perpendicular approach. We anchored there for the night, hoping that the weather would be good enough to do the helicopter flights. In the morning of the 24th we brought the ship in at the ice margin and deployed the ice raid. The weather was nice and the helicopter flew to Sachs with George Gartrell and David Scott after the completion of the EM survey. The helicopter came back with Anne Debroise. We organized an outing for the crew and scientists so that they could see the rafted multi-year ice while the ice teams finished their work. We left this site at

19h00 and sailed west toward the pack ice while completing a CTD transect (line 6000) west of station 1806.

In the morning of the 25th we began operations on multi-year ice (station M1). John did an EM survey and Nathalie deployed a beacon on the ice while conducting a short beluga survey. While some people worked on the ice the ship moved slightly off in open waters to conduct open water sampling. When we retrieved the ice raid another beacon was put on the floe where people had worked. During the night we transited to the western end of the northern transect. We approached a multi-year ice floe in the morning of 26 May, dropped the ice raid (station M2) and moved off for open water operations at station 8010. The station was finished at dinner time and we proceeded along the CTD transect (line 9000) until midnight. Full station 9008 was completed on 27 May, after which we finished the CTD transect at station 9002 and deployed a box core (9001) slightly to the southeast.

The ship entered the ice bridge in McClure Strait at midnight on 27 May and we spent the night at the edge prior to sampling the first-year ice on 28 May (station F5). The third ice beacon was deployed on this piece of ice. I sent an e-mail to Joanne Eldridge (Sachs HTC) to inform her of our plans to be in Sachs on Thursday. We left this site at noon, conducted a rosette cast and zooplankton nets, and began our transect south toward Sachs Harbour. I then realized the e-mail sent to Joanne Eldridge had bounced back so I tried with another address and got through this time. Eight CTD stations were planned along the way, but the rosette failed just before commencing the CTD cast at station 1815. Steeve attempted to fix the problem during the next 2.5 hours. The problem was initially with the carousel, which was swapped with that of the other rosette. It looked like it was working and then the multi-conductor cable failed (no power to the CTD). The cable needed to be re-spliced and it would not have been possible to sample again until we had to be in Sachs. In the morning of 29 May, Steeve confirmed that the repair was successful and that the rosette would be available the next day after the spice had dried. The rest of the line was cancelled and we sailed south.

The ship arrived in the vicinity of Sachs at 11h30 on 29 May. In early afternoon I found an e-mail from Joanne Eldridge informing us that HTC members wanted the ship to move or cancel the beluga survey and crew change because the “main bunch was arriving today”. Roger’s interpretation of the message is that the “birds are scheduled to arrive today”. Assuming that such a sixth sense exists in the community, it is puzzling that the HTC did not reply to my update of Thursday before seeing the ship. I sent an e-mail offering to move the ship a few miles in their preferred direction, and to modify the flight path of the helicopter according to their wishes, but I go no reply.

Leg 8B (David Barber)
Barber arrived on the ship on May 29 with the idea of establishing a late season fast ice camp. The exchange was don in Sachs Harbour via the Beluga survey twin otter aircraft. Two journalists also came onboard (Olivier and Tatiana). We had some communications from the community that they did now want the ship to stay around too long as the White geese were returning and we night affect their hunting. We departed that evening for station D44

May 30 was conducted at a draft station along the SW coast of Banks Island (D44). We operated a full suite of moonpool and on ice sampling. May 31 we moved further into Amundsen Gulf to another drift station (D45). Again a full suite of moon pool and on ice activities were completed (see log in the appendex or the master list (ship’s log).

On June 1 we completed the mooring station (405) in the middle of AMundsen Gulf. This station had a combination of moon pool sampling, foredeck sampling and on ice sampling. We then made our way to the Darnley Bay fast ice to begin a fast ice camp operation. We entered into the ice on the evening of June 1 and began sampling on June 2. We had a complete range of ice and moonpool sampling for both June 2 and 3.
We then moved the ship on the evening of June 3 towards the crew change location at Cape Parry. We spent the June 4 day their preparing for the crew change and then June 5 was the major crew change day. Barber remains onboard as Chief Scientist for the first part of leg 9A.

1.2. Cruise maps and station identifiers

JET, Michel and Veronique Lago acted as a 'keepers of station ID's on this leg. He produced a map showing the drift stations identifiers and has in his records a more complete description of the lats and longs of each drift station. Note that box coring may not be co-located exactly with other sampling as quite often we had to move the ship to do a box core; we did however keep the same station identifier.

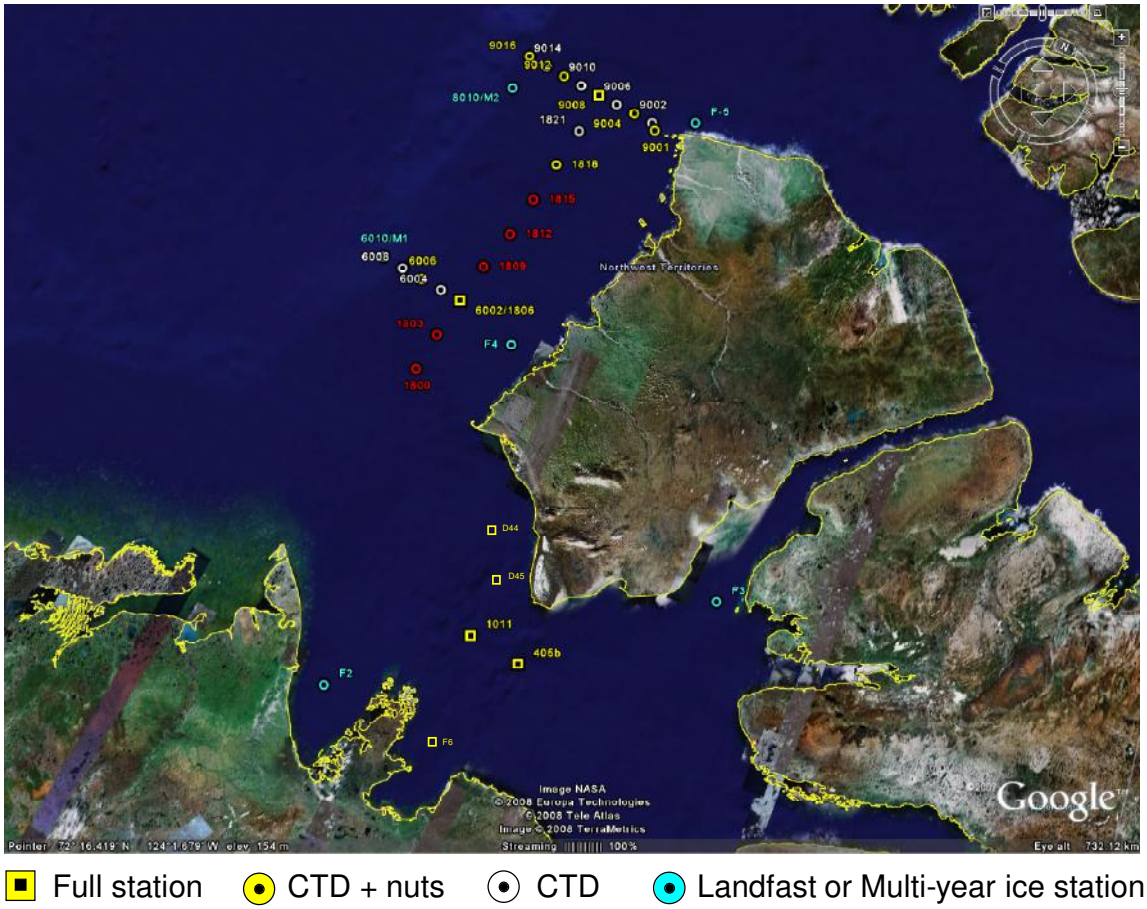


Figure 1. Drift stations completed during leg 8. Individual maps of these stations and their ID's are located in the Appendix of this report. Refer to the bridge log (appendix of this report) for specifics of locations, drift rates and timing of all events from these stations.

1.3. Cruise schedule

Science operations on this leg consisted of on ice sampling, sampling through the moonpool and sensors which collected data while underway. The ships log should be consulted for specifics of what sampling occurred when, where and at what time. Note also that we were in the drift mode of the CFL project at this time so position locations at the beginning of a station stop are not necessarily and same as those in the middle or end of that same station.

1.4. Ship Log of Science Activities

2. Team reports

2.1. Team 1

PI: Yves Gratton (INRS-ETE, 490, Rue de la Couronne, Québec)
Participants: Véronique Lago, Caroline Sévigny (INRS-ETE, 490, Rue de la Couronne, Québec)

2.1.1. CTD/Rosette

Objectives
Description of water masses and general circulation over a year in Beaufort Sea and Amundsen Gulf.

Materials
Physical parameters were recorded using a ship mounted RDInstruments Ocean Surveyor ADCP (150kHz), and a rosette frame equipped with 24 bottles of 12 L and the following sensors:

Table 1: Sensors used on the Rosette

Photo	Item	Manufacturer	Type & Properties	Serial Number
	CTD	SeaBird	SBE-911 Sampling rate : 24 Hz	
	Temperature	SeaBird	SBE 3plus Range: -5°C to + 35°C Accuracy: 0.001	4204
	Pressure	SeaBird	Accuracy: 0.015% of full range	90584
	Conductivity	SeaBird	SBE 4C Range: 0 to 7 S/m Accuracy: 0.0003	2696
	Oxygen	SeaBird	SBE-43 Range: 120% of saturation Accuracy: 2% of saturation	0420
 pH	SeaBird	SBE-18 Range: pH from 0 to 14 Accuracy: pH 0.01	0444	
	Nitrates	Satlantic	MBARI ISUS Range: 0.5 to 200 µM Accuracy: ± 2 µM	134
	PAR	Biospherical		4664
	SPAR	Biospherical		20147
	Fluorometer	Sea Point		2465
	Transmissometer	WetLab	Path length: 25 cm	CST-558DR
 Altimeter	Benthos		1061	

Method

For the whole leg, because of heavy ice conditions, the rosette was deployed from the Moonpool. CTD or Rosette casts were usually performed four times a day while stucked in the ice at 7a.m., 11a.m., 3p.m. and 7p.m. Three times, we did a 13 hours non-stop CTD sampling. Water was sampled according to each team requests. Here are examples of usual depths collected by them.

- *Nutrients* (Team 7; PI: Jean-Éric Tremblay): salinity of 33.1, chlorophyll maximum, 10, 20, 30, 40, 50, 60, 80, 100, 120, 140, 160, 180, 200, 250, 300 and every 100 m up to the bottom.
- *DIC* (Team 6; PI: Lisa Miller): salinity of 33.1, 10, 20, 30, 40, 50, 60, 80, 100, 120, 140, 160, 180, 200, 250, 300 and every 100 m up to the bottom.
- *doc/don* (Team 7; PI: Christine Michel): salinity of 33.1, 10, 20, 30, 40, 50, 60, 80, 100, 120, 140, 160, 180, 200, 250, 300 and every 100 m up to the bottom.
- *Contaminants* (Team 8; PI: Gary Stern): chlorophyll maximum, 10, 25, 50m and every 50m up to the bottom.
- *DNA* (Team 7; PI: Connie Lovejoy)
- *Microbes and Virus* (Team 7; PIs: Carlos Pedros and Roxanne Maranger): "interesting" features in the O_2, NO_3, fluorescence, temperature and salinity profiles.
- *CDOM* (Team3 ; PI: Pierre Larouche): 10, 25m and chlorophyll maximum while in the ice and 50%, 20% of light, chlorophyll maximum and 60m while in open water.
- *Pigment* (Team 3; PI: Suzanne Roy): 10, 25m and chlorophyll maximum while in the ice and 50%, 15% of light and chlorophyll maximum while in open water.
- *Primary production*(Team 3; PI: Michel Gosselin): 10, 25m and chlorophyll maximum while in the ice and 50%, 30%, 15%, 5%, 1%, 0.2% of light, chlorophyll maximum, 75 and 100m while in open water.

Sampling locations

We focused on the Amundsen Gulf and on the west of Banks island.

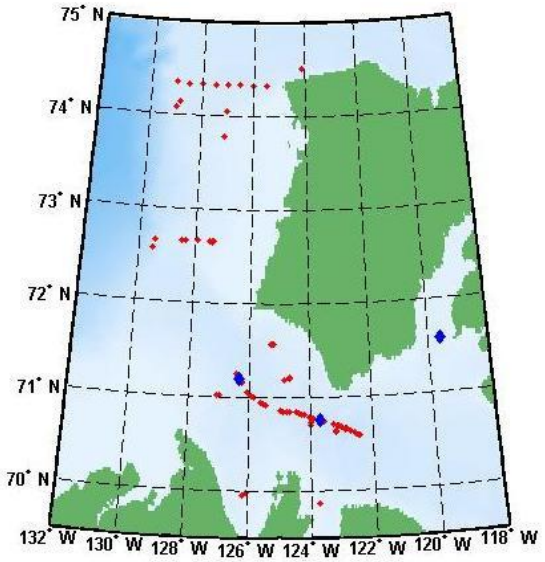

Figure 1: Positions of Rosette casts are shown as red dots and stations of 13 hours sampling are blue diamonds.

Probes calibration

Salinity: Samples were taken on many casts with small bottles of 200 mL. They were analysed with an autosal GuildLine, model 8400B. Its range goes from 0.005 to 42 and its accuracy is <0.002. The results were satisfying. The difference in between the salinity probe recordings and the samples was around 0.036.

pH: Tests were done twice using two buffers. The sensor is quite stable. Results are as follow:
Buffer 4.01 gave 4.09
Buffer 7.00 gave 7.37
Sea water is usually around pH=8, we can expect pH data to be a little over estimated.

Oxygen: Oxygen sensor calibration was performed using Winkler's method and a Mettler Toledo titration machine. Reagent Blanks was performed once, results show that chemicals are still good (m<4). We sampled oxygen on five casts. Each time, we choose five depths of different oxygen concentration and sampled it three times. The results are not satisfying; the slope of comparison between the sensor and the samples is varying. We think that the water might be sursaturated in oxygen which make it harder to analyse with the Winkler method.

Figure 2: Reagents Blanks (m=0.5600).

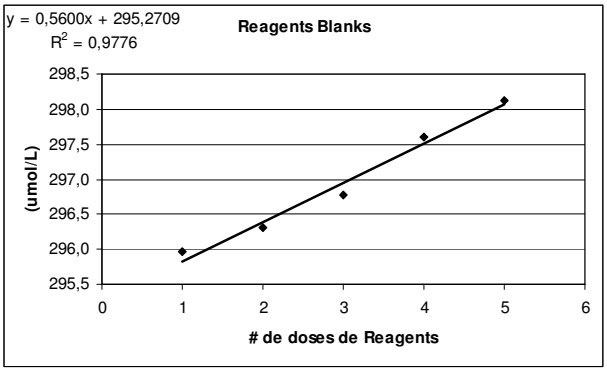

Figure 3: Relation between samples and probe recordings during cast #072 (m=1.1237).

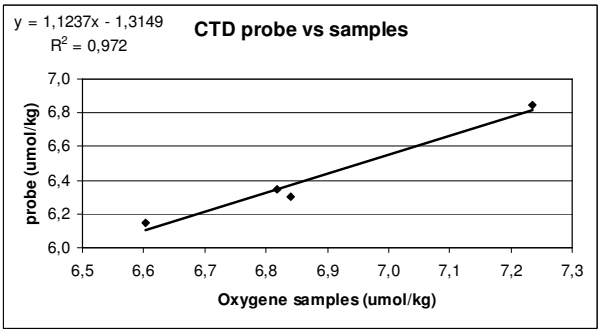

Figure 4: Relation between samples and probe recordings during cast #113 (m=1.2987).

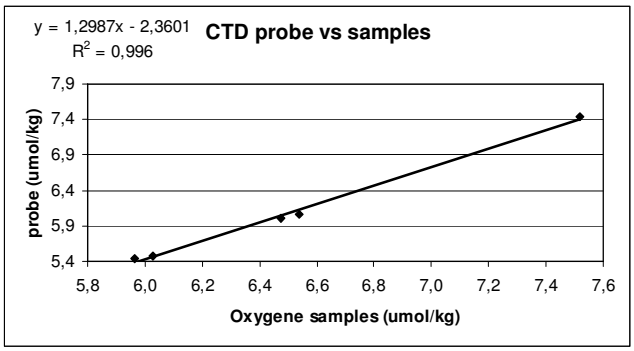

Figure 5: Relation between samples and probe recordings during cast #132 (m=0.9305).

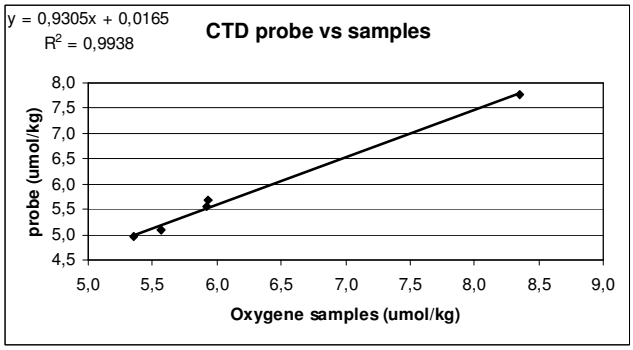

Problems

- **Sensors**
  The analysis of water samples for dissolved oxygen by the Winkler method does show stable results. This might be caused by a sursaturation in oxygen of the water at this period of the year, which makes the analysis harder. The data will probably be hard to correct.
- **Deck material (winch, A-frame, etc.)**
  The connexion from the deck unit to the sensors broke once. Therefore data from one cast are corrupted.
- **ADCP:**
  The currents were only partly measured sometimes during the leg. The ADCP could not determine the middle range of the water column currents for a still unknown reason. The ADCP also stopped receiving proper information a few times due to ice under the ship.

Available data

All information concerning the Rosette casts are summarized in the CTD Logbook. It includes cast and station numbers, date and time of sampling in UTC, latitude and longitude, bottom and cast depth, comments concerning the cast and its name. A Rosette sheet was also created for every single cast. It includes the same information than the CTD Logbook plus the bottle distribution among every sampling team. The weather information is written in every Rosette Log as well as in a meteorological logbook. For every cast, data recorded at the moment of bottle closure were averaged and recorded in the so-called 'bottle files'. Averaged data are those recorded between 3 seconds before bottle closure and 7 seconds after it. It includes the bottle position, time and date, pressure, temperature, salinity, transmissivity, chlorophyll, oxygen, irradiance and pH measurements. All those files are available on the 'Shares'.

- Rosette sheets and the CTD logbook : Shares\Leg8Rosette\logs
- Bottles files : Shares\Leg8\Rosette\btlfiles
- Plots of every cast including salinity, temperature, oxygen, transmissometer, nutrients, fluorometer and irradiance : Shares\Leg8\Rosette\plots

Between April 24th, 2008 and June 5th, 2008, 144 casts were performed.

Preliminary Results

The three "13 hour marathons" were performed on two different locations: stations 2008-D43 and 2008-F3.

Figure 6 shows temperature, salinity and oxygen data recorded on the 13 hours sampling done on station 2008-D43 on April 29th

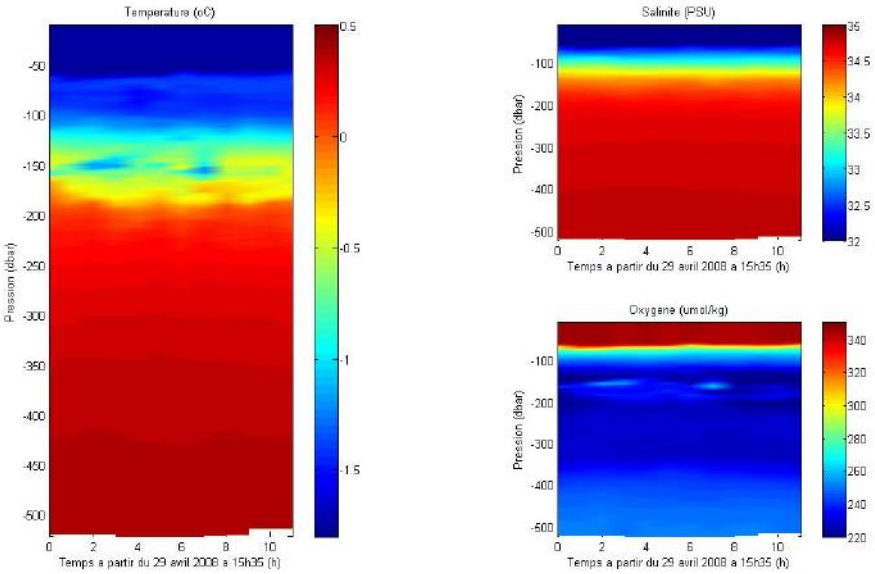

Figure 7 shows temperature, salinity and oxygen data recorded on the 13 hours sampling done on station 2008-D43 on May 5th.

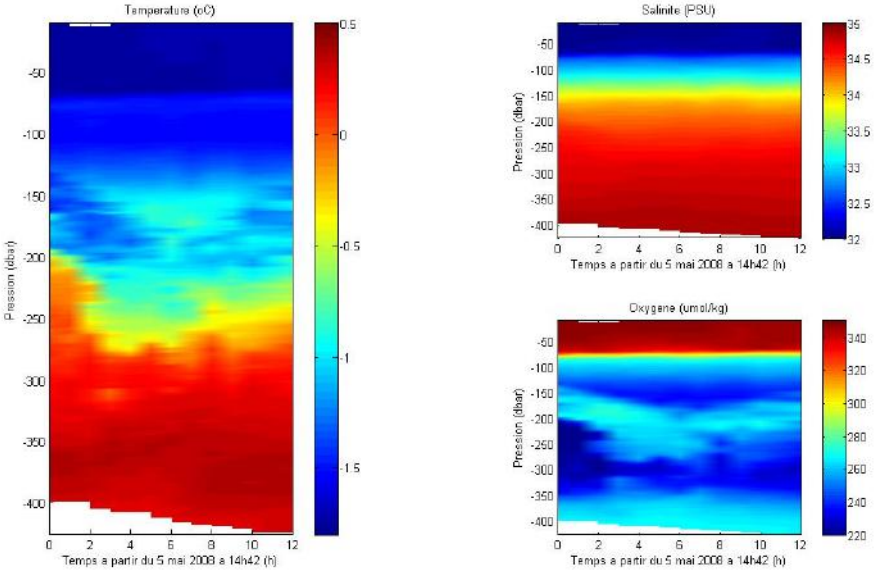

Figure 8 shows temperature, salinity and oxygen data recorded on the 13 hours sampling done on station 2008-F3 on May 20th

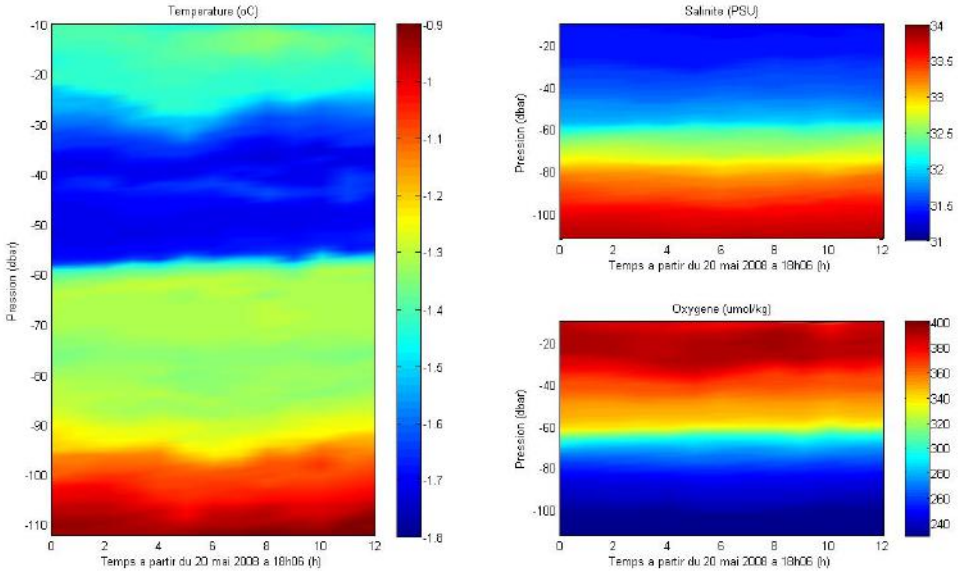
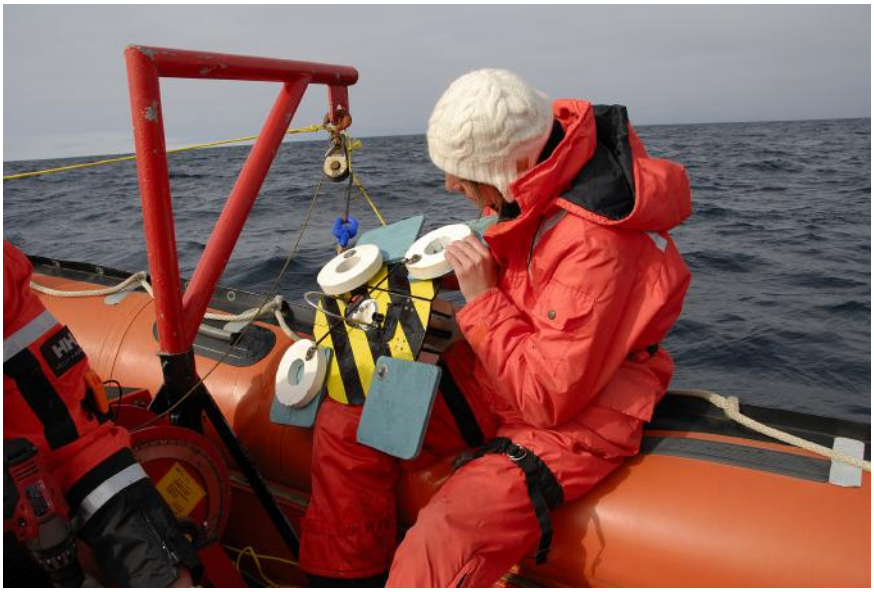


2.1.2. Self Contained Autonomous MicroProfiler (SCAMP)



The SCAMP is a CTD type profiler (see figure 6). It samples at a frequency of 100 Hz (i.e. 100 times per second). It free falls at approximately 10 cm s^{-1}, resulting in a vertical resolution of approximately one (1) millimetre, down to a maximum depth of 100 m. The instrument measures the temperature and salinity fluctuations at the micro-scale in order to estimate the turbulent mixing occurring in the water column. To properly measure (as opposed to "estimate") turbulence we should also be measuring the velocity fluctuations. Unfortunately, we do not have velocity sensors (too expensive for now). The current sensors on the SCAMP include temperature (three sensors), salinity (i.e. conductivity; two sensors) and fluorescence.

Turbulent transports and mixing are among the most important processes in natural systems. They are much more efficient and act much faster than purely diffusive (i.e. molecular) processes. By analogy with the molecular diffusive processes, turbulent mixing is often called “eddy diffusion”. The mixing energy is introduced at large scales, often by the wind at the sea surface and tides at the bottom. Turbulent mixing is called “eddy diffusion” because energy can be thought as being transferred from larger scales to smaller scales, i.e. cascading from larger eddies to smaller and smaller eddies until it reaches the molecular scale where it will be ultimately dissipated into heat. Studying turbulent processes will help us understand how the Mixed Layer (ML) if formed and how it evolves over daily, seasonally and yearly time scales. A better knowledge of the ML properties will help determine how the biological production is affected by the physical processes in the surface layer. A better understanding of the dynamics of the ML will improve our climatic forecasting abilities. Indeed, the mixed layer is the main buffer between the atmosphere and the ocean and it controls most of the heat exchange between the two. One of the major problems is that the ML is evolving hourly, making it very difficult to parameterize in larger numerical circulation models. A better understanding of the ML dynamics will improve the forecasting capacities of both oceanic and atmos-pheric models.

The table below summarizes the basic information about the SCAMP profiles obtained during Cruise 0803, i.e. in CFL leg 8. Profiles have been taken from the zodiac at the open water stations or from the moon pool at the ice stations (stations labelling DX or FX).

2.2. Team 2

2.2.1. Ice Dynamics

PI: David Barber (CEOS, University of Manitoba)

Participants: John Yackel (University of Calgary)[2]. Klaus Hochheim[1], Randall Scharien[2], Andrea Rossnagel[1], John Iacozza[1] Lauren Candlish[1], Chris Fuller[2] , Natalie Asselin[1] ([1] University of Manitoba, [2]University of Calgary)

Ground-based Scatterometer System

Sea ice physical properties vary considerably over various spatial and temporal scales, making the identification of ice types and inversion of sea ice geophysical properties using radar imagery difficult. This is particularly true in the spring melt season, when the presence of free water in the snow and in pools on the surface (melt ponds) modifies the radar signal.

As part of the Team 2 EM sampling program, a portable, fully-polarimetric, C-band (5.3 GHz microwave, University of Calgary) radar scatterometer was deployed on the sea ice for the collection of radar backscattering signatures (Figure 1). complement to larger-scale scans acquired from the ship (CEOS).

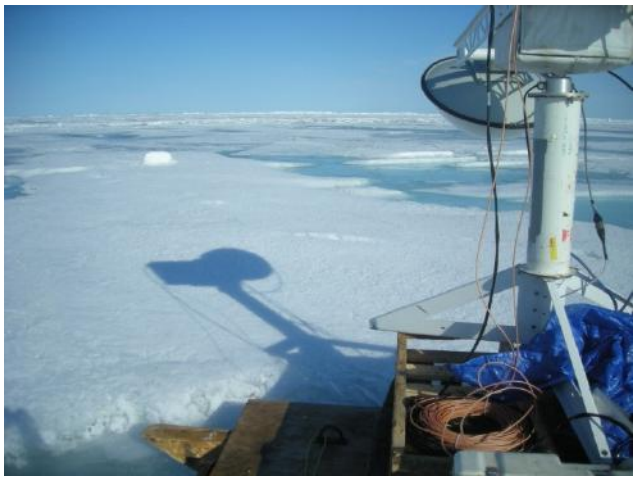

Figure 1. View from behind the ground-based scatterometer (foreground right) and field of view over a snow patch on melt ponded first-year sea ice.

A ground-based polarimetric scatterometer is used to measure complete[1] microwave backscattering signatures of specific surface features on the cm to m-spatial scale. The system is designed to scan the surface over a range of incidence angles, as well as across a specified azimuth range, depending on the size and orientation of the target of interest. It is designed with the same specifications as the ship-based scatterometer, and is used as a Data collection occurred on occasions where the ship was stationary for a sufficient length of time to enable successful on-ice assembly, sampling, and disassembly. During Leg 8B, two successful deployments were made: from May 16-18 on snow-covered landfast first year-sea ice in Franklin Bay and June 2-3 on snow and melt-pond-covered landfast first-year sea ice Darnley Bay. Microwave backscattering signatures were collected as a time series of *scans*, with each scan comprising fully polarimetric microwave backscattering coefficients (σ°) and phase information over the incidence angle range 24-64° at a 2° sampling interval. A typical scan takes 20-30 minutes depending on the azimuth range used to integrate the backscattering signature at each incidence angle.

Table 1. List of scatterometer samples acquired during Leg 8A.

Site	Date (DMY)	Y	X	Start (Local)	Stop (Local)	Scans

[1] A fully polarimetric radar measures the backscattering return in 4 transmit-receive combinations of horizontally (H) and vertically (V) polarized waves (i.e., HH, VV, HV, and VH) as well as phase information.

While operational, the following complementary data were collected within the vicinity of the scatterometer:

- Diurnal measures of snow and ice physical properties, i.e., snow pit and ice core samples (Table 2);
- Snow volume dielectric permittivity measurements;
- Qualitative assessment of snow layer properties and snow and ice surface roughness; and
- Destructive sample of snow depth within the scatterometer footprint (i.e., after moving or disassembling the scatterometer).

Table 2. Locations, dates and times of snow and ice physical property measurements made coincident to ground-based scatterometer measurements.

Darnley	6/2/2008	19:20:00	Between ship and ground scatterometer site
Darnley	6/3/2008	09:00:00	Between ship and ground scatterometer site
Darnley	6/3/2008	19:30:00	Between ship and ground scatterometer site

During each snow pit, the following variables were collected:

- Depth;
- Temperature (snow surface, 2cm interval to depth, ice surface);
- Salinity (2 cm interval to depth, ice surface);
- Density (2 cm interval to depth);
- Grain photos (2 cm interval to depth);
- Snow volume dielectric permittivity (2 cm interval to depth);
- Snow water volumetric content (2 cm interval to depth).

Snow permittivity and water volume content were measured using a Stevens Water Monitoring Systems, Inc. Hydraprobe. This probe effectively replaces the conventional capacitance plate methodology for determining snow water content and estimates of permittivity.
The scatterometer system will be re-established on the ice at the Darnley Bay ice station at the beginning of Leg 9A.

Snow and Melt Pond Distribution on Sea Ice
Summer sea ice varies considerably in its complex combination of surface types on a scale of less than one square kilometre. Deep snow, bare ice, melt ponds, open water areas, cracks, and ridges all have different physical properties that each affect the solar energy absorbed by the Arctic sea ice-ocean system differently. This research is focused on understanding the evolution of snow distribution over first-year sea ice, and the relationship of snow thickness distribution (in winter) to the melt pond distribution and morphology (in spring). Surface data will be co-located with coincident synthetic aperture radar (SAR) backscatter and other satellite-based remote sensing datasets for the purpose of improving snow and sea ice inversion property inversion algorithms.

Snow thickness distribution statistics for 12 sites of varying ice surface roughness over landfast sea ice in Franklin Bay, NWT were collected during leg 8A by Dr. John Yackel and Chris Fuller of University of Calgary (with the assistance of John Iacozza, University of Manitoba). Figure 2 shows these sites on a low resolution RADARSAT-1 SAR image, where very smooth areas appear as dark tones and extremely rough sites appear as bright tones. Each site represents the location of approximately 200 snow thickness samples conducted during leg 8A along both the downwind and cross-wind direction of the predominate snow drift pattern**.**

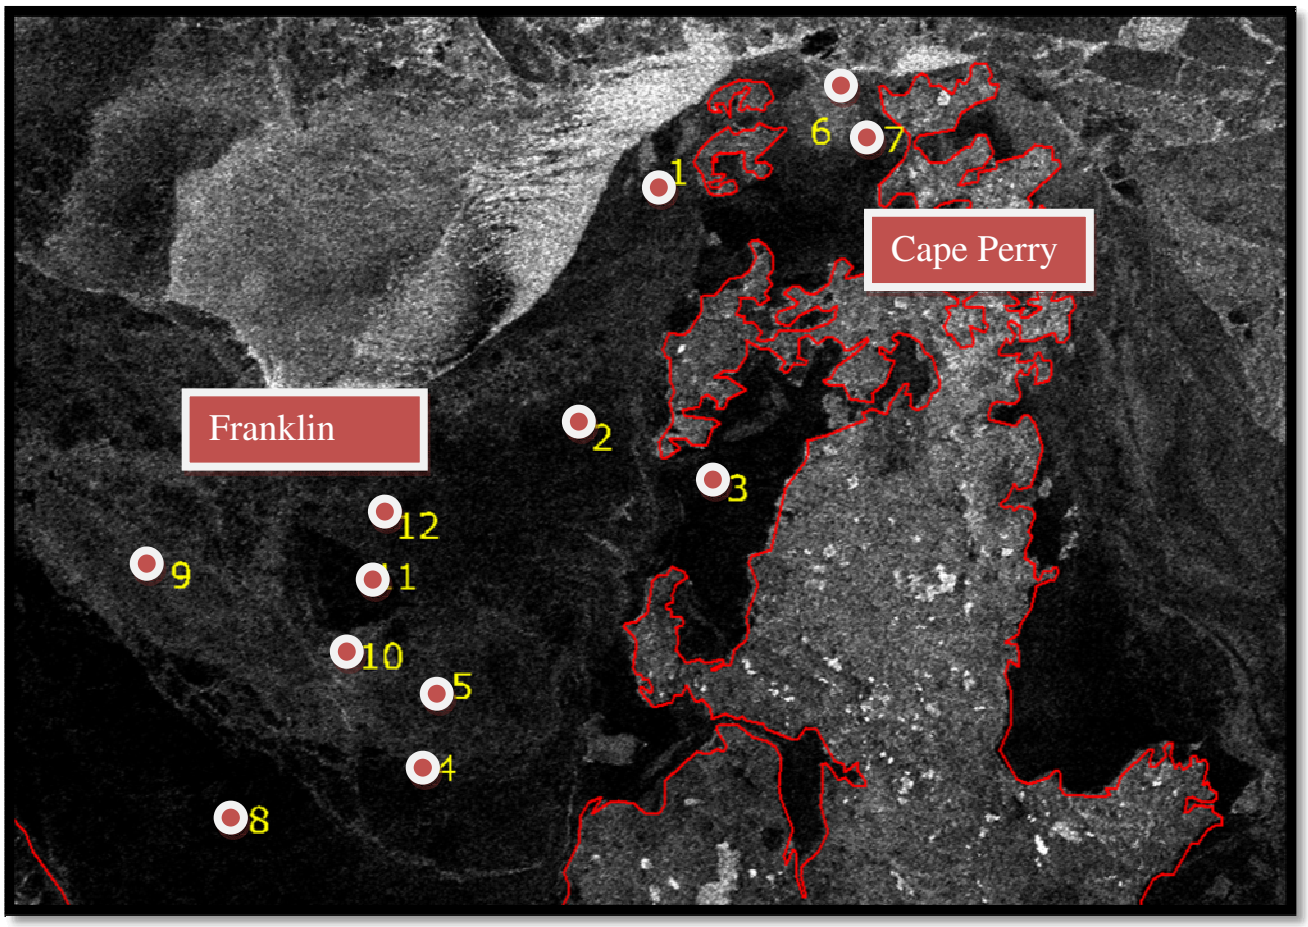

Figure 2. Distribution of snow thickness sites established during Leg 8A overlaid on a RADARSAT-1 ScanSAR (low resolution) image acquired over Franklin Bay on April 8. RADARSAT-1 image © Canadian Space Agency, 2008.

In leg 8B, 9 sites (i.e., all but sites 2, 3, and 9) were re-visited via helicopter over three flights on June 2 and 3. At each site, snow thickness and melt pond thickness distributions from orthogonal 100m long depth transects across and along the predominant drift/pond pattern were acquired. For sites where melt ponds had developed, each sample point along a transect was assigned a surface ID representing one of three predominant surface types: (1) snow; (2) melt pond; and (3) bare ice. Qualitative observations on the decay state of the snow and ice, as well as surface roughness and predominant features in a microwave scattering context, were made as well.

Snow and ice physical property (i.e., snow pit and ice core) data were acquired from 4 sites situated along a north to south gradient (sites 6, 1, 12, and 8 in Figure 2) in order to relate the decay state of the snow and ice volume across this gradient.

Ship-based EM Measurements – Scatterometer

The Kipp & Zonen tracker, which moves the scatterometer in range and azimuth, failed on May 31. The failure caused the radar to increase in incidence angle until its movement became restricted by the roof of the scatterometer shed. An assessment of the radar itself showed no apparent damage, though some of the cables were perhaps stretched beyond their normal 'comfort' range. One of the gear drive motors in the tracker also wasn't functioning properly after being counter-forced by the resistance of the top of the shed. A full gear drive lubrication procedure was executed as per the Kipp & Zonen tracker manual. The tracker was reconfigured and, after several attempts, began functioning normally again.

Pending access to the ice, the following complementary data were collected within the vicinity of the footprint of the ship-based scatterometer:

- Diurnal measures of snow and ice physical properties, i.e., snow pit and ice core samples (Table 3);
- Snow volume dielectric permittivity measurements;
- Qualitative assessment of snow layer properties and snow and ice surface roughness; and
- Destructive sample of snow depth within the scatterometer footprint (i.e., when moving or disassembling).

During each snow pit, the following variables were collected:

- Depth;
- Temperature (snow surface, 2cm interval to depth, ice surface);
- Salinity (2 cm interval to depth, ice surface);
- Density (2 cm interval to depth);
- Grain photos (2 cm interval to depth);
- Snow volume dielectric permittivity (2 cm interval to depth);
- Snow water volumetric content (2 cm interval to depth).

Snow permittivity and water volume content were measured using a Stevens Water Monitoring Systems, Inc. Hydraprobe. This probe effectively replaces the conventional capacitance plate methodology for determining snow water content and estimates of permittivity.

Ship-Based Radiometer (SBR)

Dual polarized passive MW radiometers operating at 37 GHz and 89 GHz on the port side of the ship were used to temperature brightness data on snow/ice surface. The SBR conducted at least twice daily scans to correspond with our physical sampling program. The system was operated in a scan mode, changing the incident angle from 30° to 70° using 5° steps. During transit and over night the radiometers were kept at an incident angle of 55°. A network camera was used to monitor the surface conditions at a sampling rate of 10s on a continual basis to match the footprint of the SBR. In addition, a hand-held camera is used at each site to provide more information on the surface conditions. An IR transducer measured surface temperature on a continuous basis. A summary of SBR data collected is provided in Table 4.

CTD and Optical Measurements

The objectives of this experiment are to examine potential impact of sea ice (and related environmental parameters) on light intensity under various sea ice, snow and solar zenith angle regimes during the spring transition period (Legs 7, 8b and 9a). To address this objective we will be measuring light fields (PAR) above and under the ice down to 60 m, albedo, snow properties (temperature, grain size, salinity) and upper ocean properties (conductivity and temperature) along with other relevant surface validation data (Table 5). These measurements will be done in fast ice floes as well as in leads and the marginal ice zone. The ultimate intent is to extrapolate these observations/results to regional scales.

Figure 3. A CTD and PAR profile through the snow and ice

CTD (Conductivity, Temperature, and Depth) and PAR (Photosynthetically Active Radiation) profiles were done opportunistically with a focus on different snow and ice conditions as well as different times of the day. This is to see the affect of different snow and ice regimes on PAR in the water column below the ice. Profiles were also done through melt ponds, thin ice as well as open water between floes from the skippy boat. Transects from open water to the ice edge and across floes were also done when possible. Sampling was done at different times of the day to see the effect of solar zenith angle.

Snow pits including a vertical pit photo, and snow grain photos, density and salinity were done for the top, middle and bottom of each snow pack when possible.

Snow Pits: T = temperature profile, Cap = capacitance plate, SGA = snow grain analysis, D = density Dep = Depth
ASD: DW = Downwelling, UW = Upwelling

Figure 5. Setting up the ASD to collect downwelling irradiance.

Moorings of PAR sensors were made and installed two times during the leg to examine diurnal light profiles. One series was installed for a period of 2 hours and the second one for 5 days. Each mooring went down to 50 m. To study diurnal light, temperature and conductivity profiles in the water column below the ice a melt pond site and a snow covered site were selected. Profiles down to sixty metres

were carried out every three hours for 27 hours at both these sites. This was done at station F6 from June 2 to June 3 and are called F6_D1 and F6_D2 in the previous Table.

Downwelling and upwelling irradiance as well as under ice transmitted irradiance measurements were done at most ice stations with a Licor quantum PAR sensor under different surface conditions in conjunction with Team 3. A table of sampling dates can be found in the Team 3 section of the cruise report. Downwelling and upwelling irradiance was also measured with an ASD at most sites. If there were different surface types at one location downwelling and upwelling irradiance was measured with the ASD at more than one location for each site.

HyperOCR Profiles

HyperOCR ocean profiles were conducted along flow edges, under ice and off the skippy boat in open water. These are hyperspectral profiles (256 channels, 300-800nm) of the ocean, to a depth of 50-60m. These measurements will be supplementing other optical work by Team 2; specifically measuring PAR under and adjacent to ice. Hyperspectral profiles are made during Leg 8b, are summarized in Table 6.

Table 6. HyperOCR profiles conducted during Leg 8a

Date	Station	Profile
May 31, 2008	Station D49, Two profiles, off ice edge, in close proximity to drift ice	Profile to 55 m
June 1 , 2008	Station 405, Three profiles, 1) off ice edge, 2) open water, 3) between ice edge and other floes.	Profile to 55 m
June 3, 2008	Station F6 One profile off small floe /open water, 200 mout from fast ice edge	Profile to 55 m

Figure 7. One of June 1 HYPEROCR profile sites

POPS Buoy

A POPS buoy was deployed June 2 in the fast ice (Station F6). The surface unit records air temperature, sea surface (SST) temp. barometric pressure, and incoming shortwave radiation. The profiler is programmed to conduct a CTD profile every hour. A PAR sensor was also attached to profiler.

Figure 8. POPS buoy at station F6

Helicopter-Based EM Induction System (IcePic)

The helicopter-based EM induction system (or IcePic; Figure 9) was used during leg 8 to derive snow+ice thickness and surface roughness for both mobile and fast ice in Amundsen Gulf and the Beaufort Sea area. PIC #9 (UofM) was used for all transects.

Figure 9. EM induction system mounted on the front of the helicopter.

Over mobile sea ice, the objective of this experiment is to derive edge roughness of the floes in an area approximately 5 km x 5 km. This system is being used over fast ice to examine the relationship between surface roughness, snow distribution and melt pond distribution. Thus a number of sites were sampled with this instrument during the beginning of this leg, and will be revisited again during leg 9. Sampling began on May 11 and continued until June 5, 2008. Table lists the data and location of the sampling transects during leg 8, as well as the file name for the data.

Table 7. Dates and location of the transects completed with the EM Induction system. The asterisks indicate that snow sampling was done along the transects.

Video imagery was captured along the transects in Franklin Bay on May 13, May 17 and June 2/3, as well as on the fast ice along the west side of Banks Island (May 24). The video frames were collected with an AXIS 210 Network Camera using an 4mm lens for 250 pixels across the camera's frame width providing a resolution of 1/2m at the 130m flying height. It is housed in a "Pod" along with a laser (Optec Sentinel 3100 laser) that is strapped to the helicopter skid gear. The computer program reads the flying height and helicopter speed to collect camera frames with a 50% overlap.

Atmospheric Sampling Program

The purpose of the atmospheric sampling program is to monitor cloud cover and cloud properties, upper level and boundary layer winds, temperature, and humidity.

All-Sky Camera

The all-sky camera system is used to take pictures of sky in order that percentage and type of cloud cover may be determined throughout the cruise. The camera takes pictures every 10 minutes.

Ceilometer

The ceilometer is used to measure the height of the cloud layers above the ship. The ceilometer was fully functional for Leg 8. Backups were performed at regular intervals.

Atmospheric Profiling Radiometer

The profiling radiometer is used to continuously measure the temperature, relative humidity, and pressure within the atmosphere to a 10 km altitude . The profiling radiometer has been running smoothly, with only occasional crashing of the interface software on the laptop due to a memory leak. Data collection was not affected. The profiler was calibrated with LN2 which will be valid till the end of CFL.

Radiosondes (weather balloons)

There were 12 balloon launches during Leg 8, most were launched towards the latter part of Leg 8. Balloon launches were conducted to correspond mainly with low-pressure depressions and cyclones, but a small number profiled high pressure systems, and low-level inversions. The balloon tether system, constructed by our Russian team 2 collaborators during Leg 5, was improved and employed on several occasions in an attempt to collect time-series data at

approximately 250m above the ground. Battery charge life, and changing wind conditions prevented us from collecting time series greater than 4 hours. Balloons used for tethered experiments were generally re-used immediately after as regular profiling balloons due to no storage location for the balloons.

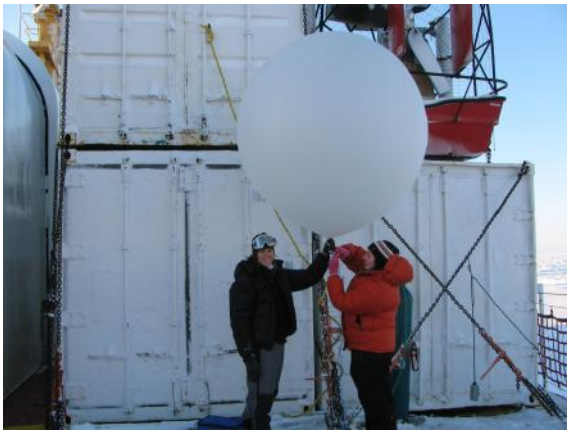

Figure 10. Attaching a radiosonde to a balloon for an atmospheric profile.

Laser Precipitation Gauge

This instrument was fully functional throughout Leg 8. The instrument continues to run as per normal, and all data has been downloaded and archived.

Ice Motion Beacons

We deployed four ice motion beacons. Two in thick first year ice and two in multi-year flows.

Figure 11. Ice motion beacon installed in a first-year ice floe.

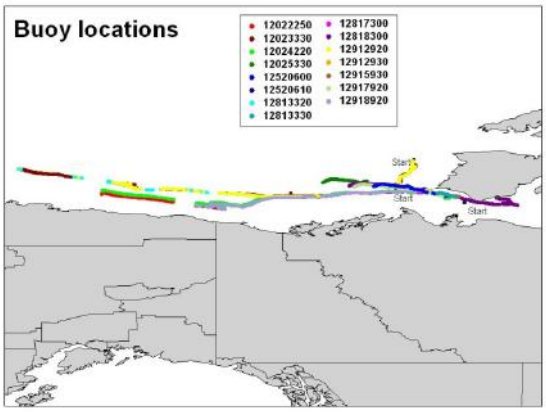

Figure 12. Ice motion buoy locations as of February 25, 2008.

Met-ocean MOBS Buoys
Two improved MOBS buoys were received, but have not been operated. The buoys are presently stored near and inside the benthic lab.

AVOS (Environment Canada MetObs System)
This system was operating normally, with the exception of a few glitches in data transmission that were worked out by the ship's electronics officer.

2.3. Team 3

2.3.1. Primary Production

PI: Michel Gosselin

Introduction
Primary producers fuel nearly all of the Earth's ecosystems by converting the sun's energy to an available food source through a process called photosynthesis. During photosynthesis, primary producers fix carbon dioxide, an important greenhouse gas, into food molecules connecting them, albeit indirectly, to our global climate. In this project we have focused our efforts to better understand physical (e.g., light) and chemical (e.g., nutrients) factors affecting primary production within the circumpolar flaw lead within the Amundsen Gulf.

In seasonally ice-covered seas, primary producers can be found in two generalized environments (habitats): (1) associated with sea ice (ice algae) and (2) suspended in the upper water column (phytoplankton). The timing, intensity and duration of primary production in these two environments are different. Both habitats play a very important and integrated role within the ecosystem. In a typical Arctic marine ecosystem, the relative importance of sea ice algae and phytoplankton follow a seasonal progression, with sea ice algae providing an initial food source for heterotrophs in early spring when the region is ice-covered, followed by a shift to phytoplankton production as the ice melts away during summer months. However, in the flaw lead system where open water can exist even in winter, the general location of primary producers is understandably much more complex. Contrasting the environments of primary producers in the flaw lead with the surrounding ice cover is a driving goal of our research. Furthermore, we have not had the opportunity to examine this dynamic region throughout the entire year, until now with the Circumpolar Flaw Lead System Study.

The Sea Ice Community
A very unique community exists within the inter-connected brine channels and brine pockets found between the larger ice crystals of the sea ice matrix. Therefore, within the sea ice, our group has focused not only on the primary producers, but on the entire community from bacteria through to meiofauna. In this section we describe the sea ice community dataset collected during leg 8 of CFL (April 24 – June 05, 2008).

Ice samples were mainly obtained via ice core extraction using 9 cm core barrels (Kovacs© Mark II Coring System). Ice core sampling was conducted at 10 stations. Depending upon the analysis needed and the snow depth available, cores were collected under low (< 5 cm), medium (8 – 15 cm) and high (> 15 cm) snow covers. General measurements taken at each core hole included snow depth, ice thickness and freeboard. Our group also worked closely in the field with teams 2, 6 and 7 to collect data on PAR albedo, transmitted PAR, vertical profiles of temperature, salinity and concentrations of various gases in the sea ice (e.g., CO_2, CO, N_2O and DMSP) and nutrients of the sea ice. The following sections are separated into sea ice algae and sea ice meiofauna.

Sea ice algae

State Variables

If available, 3 snow depths were targeted at every sampling station. The bottom 0 – 3 cm and 3 – 10 cm sections of the ice cores were collected from each snow depth. Depending on the amount of material needed for analysis and the amount of algae visible in the sea ice, 4 to 7 cores were collected from each snow depth site. One of the medium site ice cores extracted was also used for a full vertical profile. Ice cores were pooled in cooler jugs and 0.2 µm filtered seawater (FSW) was added at a dilution of 100 ml FSW per 1 cm of core prior to melting. The samples were then left to melt overnight in the cooler jugs. Once melted, nutrient (Nut) samples were taken, followed by a measurement of the salinity and total volume of the samples. It is noted that nutrient samples for FSW were collected as well as nutrient samples for additional core sections (i.e., no FSW added) which were stored in whirl-pack bags and placed in darkness to melt. Salinity, temperature and conductivity were measured on each melted sample.

Samples were filtered for determination of size fractionated (0.7 µm, 5µm and 20µm) chlorophyll *a* (chl *a*), particulate organic carbon and nitrogen (CHN), spectral absorption of particulate matter (Ap.), high performance liquid chromatography pigment analysis (HPLC), general cell identification (Cells; fixed in Lugol Acid and Formalin and to be counted via inverted microscopy), cell identification of autotrophs and heterotrophs via epifluorescence microscopy (Epi.), abundance and size class of pico/nanoalgae and bacteria via flow cytometry (Cyto.) and DNA fingerprinting of ice samples (DNA) (Table 3.1). Furthermore, at every medium snow depth site, a vertical profile core was collected for determination of Chl *a*, Cells, Ap, cyto and HPLC (Table 3.1).

Table 3.1. Data collection timeline for ice core extraction samples. L, M and H stand for low, medium and high snow depths and thin represents ice less than 70 cm thick with a 3 – 4 cm snow cover.

Rate Variables
During leg 8, samples were collected to measure carbon uptake by algae under varying light conditions via ^{14}C labeling. Increasing light intensity is plotted against carbon uptake per unit chl *a* to create Photosynthesis-Irradiance (PI) curves. These curves are used to determine parameters such as the algal photoacclimation and maximum carbon uptake per chl *a* biomass. The method involved scraping the bottom of an extracted ice core into a known volume of FSW in the field. This method minimizes osmotic stress on the algae.

The samples were also analyzed using an under ice incubation array deployed by either an under ice arm. Samples were placed into 60 ml culture flasks and covered with a range of neutral density filters used to block a known percentage of light per flask. A Licor© PAR sensor was positioned in the center of the incubation array to log incoming light during the incubation.

Unfortunately, due to the schedule that we had, we were not able to perform this experiment. We did it once, but the scintillation counter was not able to recognize the vials. These problems were unexpected, and it would have been interesting to sample more stations to understand the phytoplankton bloom versus the decline of ice algae.

Open Water Variables
During the whole leg, many open water stations were sampled. In fact, even during ice stations, we were collecting water from the rosette for the 10m and 25m depths. For the upper part of the water column, a small pump was used to collect the water underneath the ice (interface) with the help of an under-ice arm, at 2m and 5m. The chl *a,* cells stained with lugol and nutrients were collected to help our understanding of the impacts of the water column on the ice algae. Salinity, temperature and conductivity were measured on each sample (Table 3.2). Open water stations were important in our measurements to determine the beginning of the phytoplankton bloom. Before sampling the water from the rosette, a secchi disk and a PAR profile of the water column were conducted to provide us the photic zone (in %). The different depths sampled were 100%, 50%, 30%, 15%, 5%, 1%, 0.2%, chl max, 75m and 100m. Usually, the 100% and 50% were collected from the cage, due to the fact that the rosette was starting at 10m (moonpool).

Samples were filtered for determination of size fractionated (0.7 µm, 5µm and 20µm) chlorophyll *a* (chl *a*), particulate organic carbon and nitrogen (POC/PON), high performance liquid chromatography pigment analysis (HPLC), general cell identification (Cells; fixed in Lugol Acid and Formaline and to be counted via inverted microscopy), abundance and size class of pico/nanoalgae and bacteria via flow cytometry (Cyto.). Refer to the table to see which depths were sampled for each analysis (Table 3.3).

[2]Institut des sciences de la mer de Rimouski (ISMER), Université du Québec à Rimouski
chantal_lacoste@yahoo.com

The main purpose of the present investigation was to further assess the role of sea-ice metazoan meiofauna in organic fluxes in the Canadian Arctic. Specific objectives were to: (1) document sea-ice metazoan meiofaunal (metazoans between 40 µm and 500 µm living within the ice) dynamics; (2) estimate the grazing impact of sea-ice meiofauna on the bottom ice algal and bacteria standing stock; (3) identify trophic relationships in sea-ice; and to (4) quantify organic matter fluxes in sea-ice food webs. In the following sections, we report on the methods involved in the data collection during leg 8 of CFL (April 24 – June 05, 2008).

Ice samples were taken at 10 stations, some of being repeatedly sampled during the leg (Table 3.4). Three ice-core bottom sections (3 cm length) were collected for abundance, biomass and composition of sea-ice meiofauna, and bacteria abundance. Nine ice-core bottom sections were collected for the determination of isotopic signatures of fractionated particulate organic matter (POM) and meiofauna. Finally, on some occasions, nine ice-core bottom sections were also collected for nutrition experiments of copepods on phytodetritus.

Abundance, biomass and composition of sea-ice meiofauna and bacteria abundance
The bottom 3 cm of 3 ice-cores was cut, put in separate coolers and transported back to the ship. The bottom section of each ice-core was melted in 500 ml of surface water filtered through 0.22 µm hydrophilic Durapore membrane filters, at room temperature. After complete melting, 4 ml of the samples were pre-filtered onto a 40 µm nylon mesh, fixed with glutaraldehyde 25% grade II, frozen in liquid nitrogen and then stored at -80°C for the determination of bacteria abundance. The volume of the remaining melted sample was measured and then passed through 500 and 38 µm sieves, and the

500 and 38 µm screenings were fixed in 4% borax-buffered formaldehyde solution and stained with Rose Bengal for subsequent analyses.

Trophic relationships in sea-ice

For the determination of isotopic signatures of sea-ice POM and meiofauna, nine ice-core bottom sections were cut, put in separate coolers (3 sections/cooler) and transported back to the ship. The bottom ice-cores were melted in 1500 ml of surface water filtered through 0.22 µm hydrophilic Durapore membrane filters at room temperature. After complete melting, each sample was then passed through a 38 µm sieve. The animals retained onto the 38 µm sieve were separated from detritus and microalgae (here identified as POM) and identified at the taxon level. Then, POM and pooled animals of each taxon were filtered through precombusted (500°C, 5 h) Whatman GF/F filters. The filters were placed in petri dishes and dried at 60°C for 48 hours and then stored at room temperature for further analyses. The same procedure was applied to the sample smaller than 38 µm.

Quantification of organic matter fluxes in sea-ice food webs

For the quantification of organic matter fluxes in sea-ice food webs, nine ice-core bottom sections were cut, put in separate coolers (3 sections/cooler) and transported back to the ship. The bottom ice-cores were melted in 1500 ml of surface water filtered through 0.22 µm hydrophilic Durapore membrane filters at room temperature. After complete melting, each sample was then passed through a 38 µm sieve. The animals obtained onto the 38 µm sieve were separated from detritus and microalgae and identified at the taxon level. Among these animals, *Halectinosoma sp.* were harvested for feeding experiments (pulse-chase technique) on phytodetritus using the experimental procedure described in Charles (1994).

Program of Maike Kramer and Annette Scheltz
Institute for Polar Ecology, University of Kiel, Germany

During legs 7 and 8 of the CFL project, ice samples were taken for studies on diversity, abundance and feeding ecology of sympagic meiofauna (metazoans > 20 µm living within the ice) (Tables 3.5 and 3.6). Ice cores were taken on seven ice floes and five fast-ice sites, using an engine-powered KOVACS ice corer (internal diameter 9 cm). Every 3-10 days, five ice-core bottom sections (5 cm length) were taken on a site of non-deformed ice, generally with medium snow cover (4-18 cm), nearby the PAR measurement area, for measurement of algal pigments (bottom section 1) and for analyses of meiofauna diversity, abundance and biomass on fixed (bottom section 2) and fresh samples (bottom sections 3-5). Once per floe or fast-ice site, one full ice core, cut in sections of 2-10 cm, was taken instead of bottom section 2 for analyses of meiofauna abundance and biomass on fixed samples with respect for vertical distribution. On the same sampling day, further three ice-core bottom sections (3-5 cm length; bottom sections 6-8) for analyses of meiofauna *in situ* gut contents were taken at sites with high, medium and low snow cover. Further ice samples, including ice-core bottom sections (3-10 cm length), ice underside (2-5 cm thick layer) scraped from blocks of ice, and pieces of ice picked up from the water next to the ship using the ice cage, were taken in order to gain meiofauna organisms and sympagic ciliates for taxonomy, fatty acid analyses and feeding experiments.

Bottom section 1 was melted in the dark at +4 °C and filtred on a Whatman GF/F glasfibre filtre; algal pigments were extracted in acetone in the dark at +4 °C, and chlorophyll *a* and phaeopigment *a* were measured fluorometrically. Bottom sections 6-8 were immediately placed in 50 ml of 0.2 µm filtred sea water (FSW) and shaken gently for one minute to flush out meiofauna organisms. The liquid was sieved on a 20 µm gauze, and the samples were fixed in picric acid formaldehyde (PAF) and stored at +4 °C. In the home laboratory, meiofauna will be sorted from these samples and cut in half, and the gut content will be analysed using a scanning electron microscope. All other ice samples, as well as the remains of bottom sections 6-8, were melted in an excess of FSW (200 ml per 1 cm of ice core) at +4 °C and enriched over a 20 µm gauze. Bottom section 2 or sections from the full ice core were then fixed in borax-buffered formaldehyde (37 % formaldehyde added to the sample, final concentration 2 %). These samples will be sorted at the home laboratory, and organisms will be measured; bulk abundances of meiofauna and ciliates will be determined, and biomass will be calculated according to Friedrich (1997). Bottom sections 3-5 were sorted onboard at +4 °C within two days after melting, and bulk abundances of meiofauna and ciliates were determined. All other ice samples were sorted onboard at +4 °C within a few days after melting.

Part of the organisms sorted from the samples onboard were preserved in formaldehyde (2-4 %), PAF or 95 % ethanol for later taxonomical and morphological studies. For fatty acid analyses, alive animals were rinsed by transferring them into fresh FSW several times, were then transferred onto a pre-combusted Whatman GF/F filtre, rinsed with MilliQ water, and stored at -80 °C. In the home laboratory, the samples will be extracted in dichloromethane:methanole (2:1 v:v), transesterificated and analysed in a gas chromatograph. The fatty acid composition will provide information on in *situ diets* (e.g. the degree of carnivory).

For determination of feeding preferences and ingestion rates, feeding experiments have been conducted onboard during leg 8, and will be carried on at the home laboratory. For this purpose, cultures of sympagic meiofauna and ciliates have been established. Sympagic meiofauna has been reared on a mixed diet of sympagic algae and ciliates isolated from melted and enriched ice samples; sympagic ciliates have been reared on a mixed diet of sympagic algae. In predation experiments, ciliates or other meiofauna taxa are offered as prey to a specific meiofauna taxon. Every 2-5 days, prey individuals are counted, the state of predator individuals is checked, and consumed prey as well as

dead predators are replaced, in order to keep the predator and prey densities constant over the duration of the experiment. In grazing experiments, individuals of a specific meiofauna taxon are placed in vials filled with a suspension of sympagic algae and ciliates. Most of the algae and part of the ciliates settle down on the bottom of the vial after short; this setup thus simulates *in-situ* conditions, where meiofauna graze on surfaces rather than in suspensions. At the end of the experiment, the grazers and part of the faecal pellets are removed, rinsed and fixed for microscopic studies and measurements at the home laboratory; algae and ciliates are resuspended and fixed with lugol solution for cell counts at the home laboratory. Both predation and grazing experiments are carried on for a couple of weeks. Comparison with controls (prey without predators / food suspension without grazers) will allow the calculation of ingestion rates (consumed food per predator / grazer and time, expressed as individuals or biomass). Setups with different predator / grazer and food densities will provide information about functional response and concurrence. During leg 8, predation experiments have already been conducted with harpacticoid copepods as predators and ciliates as prey (four different prey densities); grazing experiments have been conducted with the same copepod taxon as grazers (three different food suspensions).

Table 3.6. Samples for algal pigments and abundance, biomass, gut contents and fatty acid composition of meiofauna. Numbers are numbers of replicates. Chl : chlorophyll *a* and phaeopigment a in 5 cm bottom sections of ice cores; A: meiofauna abundance in fresh 5 cm bottom sections of ice cores; AB: meiofauna abundance and biomass in fixed 5 cm bottom sections of ice cores; Abvp: vertical profiles of meiofauna abundance and biomass from full ice cores; G: gut contents of sympagic meiofauna; Qual: qualitative samples for diversity, feeding experiments and fatty acids (see below); L: low snow site; M: medium snow site; H: high snow site; T: thin ice; IC: ice cage; IU: ice underside from blocks; FA: fatty acids

Phytoplankton communities

Viability and photoprotection of phytoplankton communities (Eva Alou Font)

Institut des sciences de la mer de Rimouski (ISMER), Université du Québec à Rimouski
eva_alou @yahoo.com

Cell viability is a poorly known process in the ocean. Viruses and bacteria are implicated in cell mortality but cell death (e.g. apoptosis) can also be important. Recent work suggests than cell viability is strongly determined by the level of photo-protection in phytoplankton (Van del Poll et al., 2005).

With rapid global warming in polar environments ice reduction and melting should lead to increased irradiance in surface waters. Phytoplankton cells previously acclimated to lower light levels may then have insufficient photo-protection and consequently suffer significant mortality. Recent work linked cell survival with nutrient depletion in oligotrophic waters (Agusti et al., 2006).

The objective of the project is to examine the flaw lead system and land fast ice in the Canadian Arctic during Spring time focusing on the following specific hypothesis:

1) To test whether photo-protection is a major determinant in changes in cell viability and this will contribute to difference between the composition of phytoplankton population from the flaw lead system and the land-fast regions.

2) To test whether cells from the more nutrient-limited regions show lower viability compared to nutrient-rich regions, when exposed to high surface irradiance.

Objectives:

1) Cell viability quantification.
2) Test cell photoprotection (Pigments, D1 protein cycle) vs. changes in viability.
3) Test nutrients vs changes in viability.

To reach these objectives, we will measure through the program the following parameters whenever possible:

1) Transparency of the water with a Secchi disk (to choose the right depths in the rosette).
2) Downwelling irradiance vertical profiles (UVb, Uva, PAR).
3) The pigment composition of phytoplankton with the high performance liquid chromatography method (HPLC).
4) Cell viability (Enzymatic technique and stain).
5) D1 protein.
6) Photosynthetic response (Xe-PAM).
7) Ratio of variable to maximum fluorescence Fv/Fm as a measure of the cell physiology activity (fluorometer).

Leg 8 methods

- Water samples were taken from April 29 until June the 3 under the thinner ice of a refreezing flaw lead close to the southeast coast of Banks Island at station D43. Samples under the ice were taken using a pump and a hose lowered through a small hole perforated in the thin ice with a handheld ice auger at surface level and 5 meters. Other samples under the ice where taken with the rosette, at 10 meters, 25 meters and depth of maximum chlorophyll when it was present.

- In open water stations water samples where taken with the rosette regarding the transparency of the water measured with the Secchi disk, normally at 50 % irradiance, 15% 1% and chlorophyll maximum when was present.

- Samples for HPLC technique were filtered through 25 mm GF/F filters with a maximum of 2 L each depth and then stored in liquid nitrogen on board.

- Samples for protein D1 were filtered through 25 mm GF/F filters with a maximum of 2 L each depth and then stored in liquid nitrogen on board.

- Cell viability was measured for each depth for posterior epifluorescence microscopy analysis.

- Vertical radiation profiles where done in each open water station.

Conclusions

The CFL leg 8 operations where completed during April 29th and June 2nd.We particularly thank the crew members and the rest of the members of team 3 who helped with some operations.

Remote sensing (Corinne Bourgault Brunelle)
Institut des sciences de la mer de Rimouski (ISMER), Université du Québec à Rimouski
gococogo@hotmail.com

Rationale
To understand and to monitor biophysical processes in complex coastal waters it is necessary to use remote sensing methods. CASES measurements showed that optical properties of the Beaufort Sea and the Amundsen Gulf region are dominated by the freshwater outflow from the Mackenzie river leading to a bias in the estimation of phytoplankton biomass using remote sensing data. There is thus a need to develop specific methods to make more effective use of remote sensing data. The building of a database of inherent optical properties relating a wide variety of physical and biological conditions is a crucial step towards this goal.

Objectives

The general objective of our team is to study the relationship between the spatial and temporal distribution of the phytoplankton and the physical environment in the canadian Arctic with an emphasis on the Beaufort Sea and the Baffin Sea using remote sensing data.

Specific objectives for the CFL 2007-08 cruise are:

- The estimation of the ability of current bio-optical algorithms to measure chlorophyll-a concentration and species discrimination;
- The development of specific algorithms for a variety of ocean color sensors which will in turn provide a better understanding of the Beaufort Sea and the Baffin Sea physical and biological processes;
- The analysis of light absorption properties of arctic phytoplankton.

To reach these objectives, we will measure throughout the program the following parameters whenever possible:

(1) the transparency of the water with a Secchi disk;
(2) vertical profiles of inherent optical properties (light absorption and transmission, backscatter light, volume scattering function, particle size spectra, phytoplancton fluorescence, CDOM fluorescence, temperature and salinity using a custom built optical profiler system;
(3) the pigment composition of phytoplankton with the high performance liquid chromatography method (HPLC);
(4) the algal pigments light absorption;
(5) the total suspended matter and its partition into organic and inorganic matter;
(6) the chromophoric dissolved organic matter concentration.

Leg 8 methods

- Water samples were taken from April 26 to June 2 under thinner ice and in open water across the Beaufort Sea. A time series was made at station D43 and F2 where the ship was parked into the ice. Samples were taken using a pump and a hose lowered through a small hole perforated in the thin ice with a handheld ice auger. Samples were taken at depths of two and five meters from the surface water level. Two other samples were also taken using the rosette system at depths of 10 and 25 metres. Measurements were also made at other locations throughout the area in open water, fast ice and drift ice. Samples were taken West to Est and North to south of the Beaufort sea. In open water station, samples were taken at depths of 1 %, 10 %, 50%, 100% of surface irradiance, 60 meters and at the chlorophyll max.

- Filtration were performed for chlorophyll determination (HPLC techniques), a_{ph}, total suspended matter (TSM) and chromophoric dissolved organic materiel (CDOM).

- For chlorophyll-a, and algal pigments, water samples (up to 2.5 litres) were filtered through 25 mm GF/F filters, flash freezed and stored in liquid nitrogen on the ship. Samples will be transported south for analysis.

- CDOM samples were filtered using 0.2 µm Anotop® syringe filters (Whatman) and collected into 60 ml acid-cleaned amber glass bottles. The bottles were stored frozen (-20 ˚C) in the dark on the ship. Samples will be transported south for analysis .

- Total suspended matter was measured by filtering up to 2 litres of water using pre-weighted 25 mm GF/F filters. The filters were stored on the ship at –80 ˚C, to arrest pigment degradation (Sosik, 1999), and will be transported south to complete the analysis.

Samples of aph and CDOM will be transported south for analysis at the end of the leg.

Detailed sampling activities up to June 2 are summarised in the Appendix.

Conclusion

The CFL LEG8 operations were successfully completed between April 24 and June 2. This was a good leg that allowed to measure optical properties during the phytoplankton bloom which arrived at week 2 and 3. The chiefs scientists were comprehensive of the particular needs of the optics team.

Appendix: Sampling information: Refer to the CTD-Rosette logs for the location and timing of the rosette sampling.

2.4. Team 4

2.4.1. Zooplankton, Fish Acoustic and Ecology

PI: Louis Fortier
Participants: Caroline Bouchard (U. Laval), Marc Ringuette (U. Laval), Steeve Gagné (electronic technician from U. Laval) and Jacques A. Gagné (Institut Maurice-Lamontagne)
Written by: C. Bouchard and J.A. Gagné (with some copy-paste from previous team four reports)

Introduction
The fragmented, thin, and often absent ice cover in the flaw lead allows solar radiation to reach the surface layer of the ocean where it triggers photosynthesis by microscopic algae. Team 4, Pelagic and Benthic Food Web, investigates how and to what extent microalgae growing in the flaw lead are consumed by the zooplankton and the benthos. Our simple hypothesis is that, relative to adjacent ice-covered regions, enhanced algal production in the flaw lead translates into biological hot spots where higher zooplankton and benthos production and abundance prevail. We also investigate how the Arctic cod, a central species in the Arctic food web, uses the flaw lead for feeding, overwintering, reproduction, and as a nursery ground for their young stages (http://www.ipy-cfl.ca/page1/page1.html).

General objectives
Our sampling program is derived from that of ArcticNet project 1.4 led by Dr. J.-É. Tremblay (U. Laval), 'Marine productivity and sustained exploitation of emerging fisheries', whose overarching goal is to assess the impact of sea-ice cover reduction and increasing sea temperatures on biological productivity, fisheries resources and marine mammal populations of the coastal Canadian Arctic. Since the beginning of the CFL field program last October, we focus on how physical processes moderate biogeochemical processes within the changing northern flaw lead ecosystem in the Amundsen Gulf - Banks Island area. The objectives of the team for leg 8 were to continue the work conducted during previous legs from the moon pool and to initiate the open water season by deploying zooplankton nets from the front deck (double (horizontal) and quadruple (vertical) 1-m^2 nets). We concentrated our sampling efforts on pelagic secondary producers as well as on larval, juvenile and adult Arctic cod. Our multidisciplinary ArcticNet-CFL team is strongly linked with Team 7 (Carbon Fluxes – Tremblay) of the CFL program.

The primary objectives of our team during CFL-8 were:
1-To assess zooplankton / fish abundance and diversity by using various sampling devices.
2-To track zooplankton / fish biomass and distribution with the EK60 Echo sounder, nets and traps.

Our secondary field objectives were to collect and use zooplankton samples to:

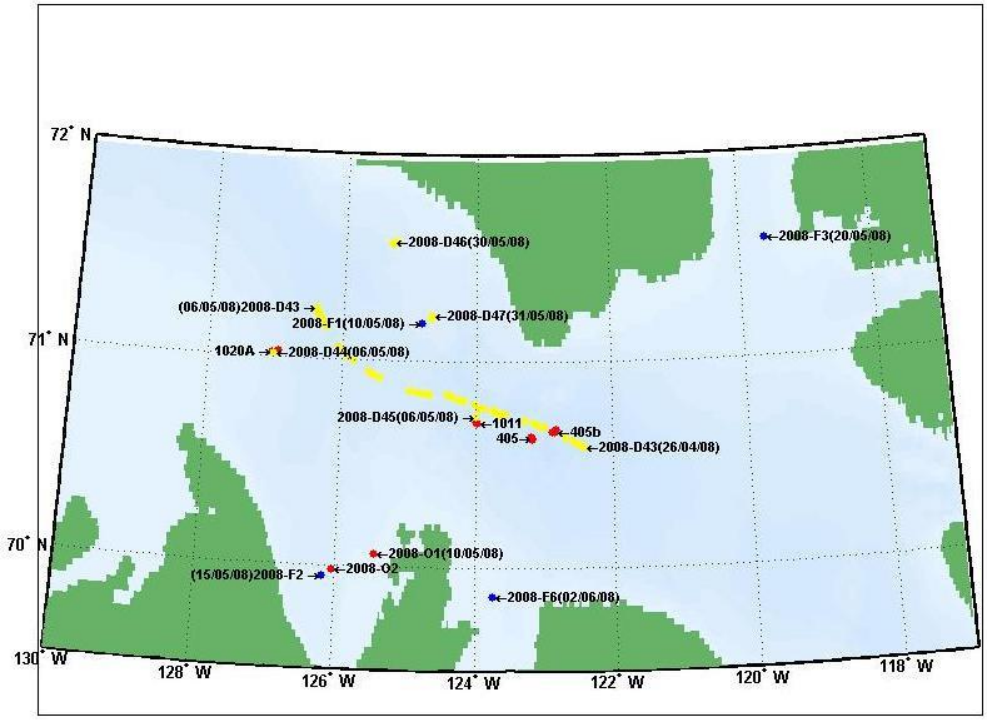
- investigate the cycling of contaminants by zooplankton and fish (G. Stern, U. Manitoba);
- identify the sources and pathways of omega-3 in the Arctic marine food web (J. Michaud, E. Dewaily and L. Fortier, U. Laval). This project is linked to the CFL-URSUK program and ArcticNet theme 1.5, focusing on the importance of omega-3 fatty acids in the traditional diet of Inuit communities;
- assess the biomass and respiration rates of the zooplankton community by the Electron Transfer System (ETS) activity at specific stations (G. Darnis and L. Fortier);

- collect samples for stable isotope analysis of the food web structure and carbon fluxes; this is a joint project between Teams 4 and 7 of CFL (A. Forest, L. Fortier, J-E. Tremblay);
- measure copepod *in-situ* egg production (EPR) and gonad maturation of *Calanus glacialis*, *C. hyperboreus* and *Metridia longa* (M. Ringuette, G. Darnis, L. Fortier);
- validate the daily increment deposition on the otoliths of larval Arctic cod using a fluorescent marker (C. Bouchard, L. Fortier).

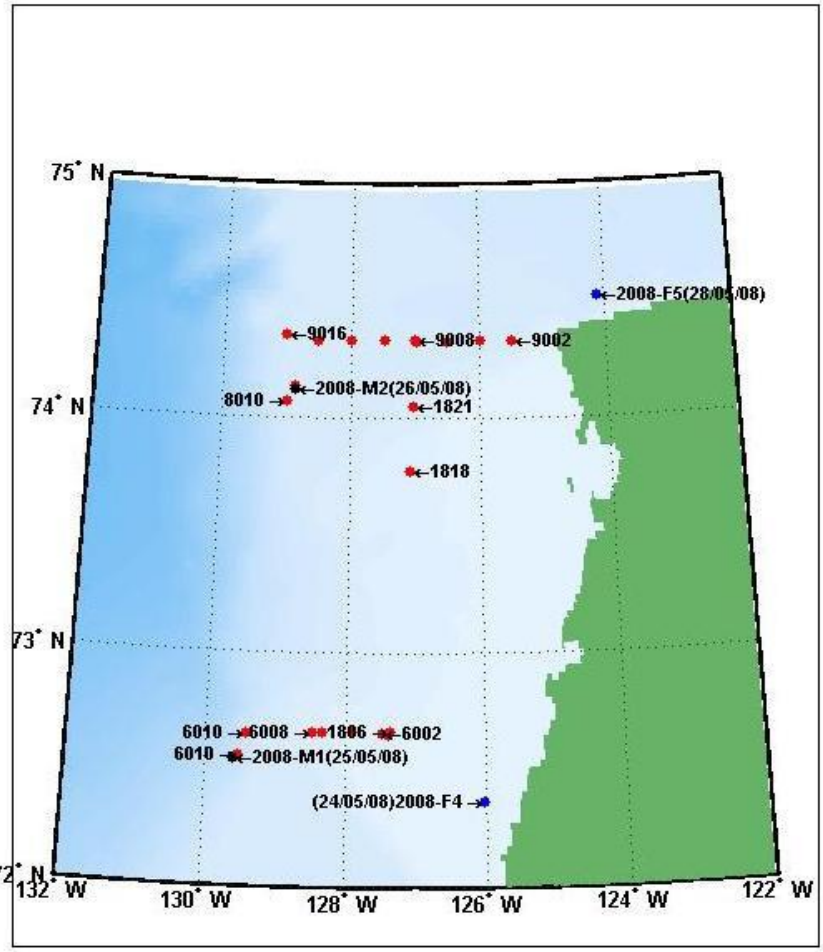
Sampling program

Leg 8 started in a drifting mode in an ice floe which we were supposed to leave a couple of days after the beginning of the leg. Because of the small size of our team (two people) and the planned short period of time at this station, we did not install the equipment for ice work. Departure from this drifting station was delayed however until May 6 because of unfavourable weather conditions. This 11-day period was devoted to moon pool sampling with one Hydrobios and at least one 1-m^2 vertical net cast per day (Table 2 and 3). We then transited to Cape Parry, initiating on the way the 2008 open water season and catching 3 Arctic cod larvae with the 2 x 1-m^2 zooplankton net. During the next two days spent in land fast ice near Cape Parry (depth ca. 50 m) for logistical operations, we dug out a 1-m^2 hole in the ice for plankton and gill net deployments (Table 5 and 6). We did not catch adult fish in the gillnet but the zooplankton samples provided us with our first live Arctic cod larvae which we used to initiate our marking experiment. Since Cape Parry appeared to be a good area to sample Arctic cod larvae, we performed a horizontal tow with the 2 x 1-m^2 zooplankton net just after leaving the F1 fast ice station (Fig. 1a). This cast brought us some 1800 Arctic cod larvae (Table 9). Zooplankton nets were again deployed from the foredeck at two open water stations (O1 and O2) before the ship was parked in Franklin Bay fast ice (station F2), near the CASES overwintering site; we resumed moon pool operations for the next five days during which we set the fish trap for two successive nights, once down to 10 m where we caught three 1 or 2 year-old juvenile cod and once just off the bottom (180 m) where we did not catch anything. At this station, a total of 17 vertical tows with the 1-m^2 zooplankton net and four Hydrobios deployments resulted in the catch of 122 Arctic cod larvae (Table 9) from which 58 were kept alive. On May 19, we sampled at station 405b (CASES CA-18) where a mooring is deployed. We set the fish trap once more that night with no catch. The next station was a full station (1011) in the open water of the flaw lead at the edge of the remaining pack ice near the southwest corner of Banks Island. We then proceeded north into the flaw lead where we completed two cross-lead transects between the land fast ice off Banks Island and the pack ice (Fig. 1b). We sampled at two open-water stations on each of the transects (stations 1806, 6010, 8010 and 9008) and caught a total of 69 Arctic cod larvae. Back in the ice, we caught 19 larvae in the fast ice of McClure Strait (station F5) and 6 at drift station D45 three days later. We then sailed back south towards Darnley Bay stopping over for a full open water station near mooring site 405 where we caught 42 larvae. Finally, we moved into the ice in Darnley Bay (station F6) where we caught only two larvae. The 30 m gillnet was deployed one last time for the leg about 100 m off the starboard side of the ship, vertically from the bottom of the ice in 70 m of water. The fish trap was set overnight just below the hull of the ship. We caught one adult cod in the trap and nothing in the gillnet. These concluded our sampling program for leg 8.

Figure 1. Location of stations visited during CFL leg 8.
a) Amundsen Gulf



a) West of Banks Island



1) Description of the sampling devices used during leg 8

a) Rosette. Samples to investigate the vertical distribution of the micro-zooplankton were collected from the rosette only once during leg 8.

b) 1-m^2 square net. A 1-m^2 square metal frame rigged with a 200 µm mesh plankton net, an external 10 cm diameter 50 µm net and equipped with a TSK flow meter. This instrument is used to obtain integrated water column samples. Downward and upward winch speeds are 40 and 30 m/min respectively. Quantitative samples from both nets for taxonomy and abundance estimates are preserved in formaldehyde. Qualitative samples (i.e. 'live tows') are also collected to obtain animals for contaminants, lipids, EPR and ETS studies.

c) Hydrobios. Multi-depth plankton profiler equipped with nine 200 µm-mesh nets (opening 0.5 m^2) for depth specific sampling of the water column. The Hydrobios is also equipped with a CTD to record water column properties while collecting biological samples. Downward and upward winch speeds are 40 and 30 m/min respectively. For most casts, the net collection was preserved in formaldehyde for taxonomic analysis. However, the content of each net from some deployments was divided 50% for taxonomy (4% buffered formaldehyde), 25% for biomass estimates and 25% for ETS analysis.

d) 1-m^2 ring net. A 1 m diameter metal ring equipped with a 200 µm mesh net, an external 10 cm diameter 50 µm net, a central GO flow meter and a RBR CTD. This net was deployed three times from a hole in the ice at proximity of the ship but at a site not influenced by its presence. The net was lowered manually to the bottom and pulled up by a snowmobile.

e) Monster net (Fig. 2a). Four 1-m^2 metal frames attached together, one rigged with a 1-m^2 500 µm mesh net and a GO flow meter for contaminant sampling, one with a 1-m^2 200 µm mesh net and a TSK flow meter for abundance measurements, two with a 1-m^2 200 µm mesh net without a flow meter for "live" sampling, and an external 10 cm diameter 50 µm net. The gear is deployed vertically from 10 meters off the bottom to the surface.

f) Tucker net (Fig. 2b). Two 1-m^2 metal frames attached together each rigged with a 1 m^2 500 µm mesh net, an external 10 cm diameter 50 µm net and equipped with a TSK flow meter. The gear is deployed obliquely to 90 meters or less (depth determined by cable length and angle).

g) Fish trap (Fig. 2c). Commercial fish trap (1.5 m x 1.5 m x 1.0 m) lowered at the desired depth from the moon pool and set overnight to catch juvenile and adult fish.

h) Trammel gill net (Fig. 2d). Three-layered trammel net, 30 m long and 1.8 m wide, with stretched mesh size of 2.9 and 6.4 cm for the internal and external panels respectively. It was especially designed to be deployed vertically from the surface to collect juvenile and adult fish.

i) Mesopelagic fish trawl. A single-warp pelagic trawl 37 m long with a 49 m^2 mouth opening and mesh sizes decreasing from 30 cm at the mouth down to 5 cm in the cod end which is covered with 9 mm mesh liner. Deployed from the port side of the foredeck, it is designed to catch juvenile and adult fish. The trawl was prepared early on during the second half of the leg but never deployed for the lack of any sign of sufficient pelagic fish concentration on the EK-60 echosounder.

2) Sampling events during leg 8

Overall, 112 sampling events occurred from which 69 samples were preserved for taxonomy. Samples from the 'live tows', were used for further analyses and laboratory experiments as described below. Samples for lipid and stable isotopes analyses were placed in cryovials and stored at -80˚C. Other samples were preserved as a *bulk* at -80˚C for later gut fluorescence measurements. All these samples will be sorted and analysed at Laval University. Samples of ice algae were also collected upon request for lipid analysis. Samples for contaminants were sorted and kept by Dr. Stern's team.

Laboratory analyses

1) Egg production rate experiments (EPR)

Copepod *in-situ* egg production rate (EPR) were monitored by incubating the females of three species (*Calanus glacialis*, *C. hyperboreus* and *Metridia longa*) at 0°C, a temperature similar to that they experience at depth. The results from the experiments conducted during leg 8 show that the egg production season is over for *C. hyperboreus* but still underway for *C. glacialis* and *Metridia longa*.

2) Biomass and Transfer System (ETS) activity

Samples were sorted for biomass and ETS activity assays on several occasions (Table 2, 3 and 7). At these stations, each Hydrobios net was subdivided: 50% for taxonomy (i.e. preserved in formol), 25% for population biomass estimates and 25% for ETS activity measurements. For biomass estimates, the

sub-sample (i.e. 25% of total sample) was fractionated with sieves in > 1000 µm and < 1000 µm size classes; these fractions were preserved at -0˚C. Sub-samples for zooplankton population ETS activity assays (i.e. 25% of the total sample) were also sieved through the same two size fractions. As no Sanyo incubator was available for the ETS experiments, samples were incubated in a Pyrex plate filled with water and heated to 40˚C on a hot plate. Temperature of this 'hot tub' proved to remain constant during the required incubation time. ETS experiments were also performed on individual copepods (females and copepodite stage 5) of *Calanus glacialis*, *C. hyperboreus* and *Metridia longa*.

3) Respiration experiments

To derive respiration from the activity of the Electron Transfer System (ETS), a ratio of respiration on ETS activity is required. Thus incubations were carried out to measure oxygen consumption of copepods in sealed chambers. The handheld oxygen meter that we started to use on leg 6 proved to be very easy and practical to use for such measurements.

Acoustic monitoring

The Simrad EK-60 Echosounder of the Amundsen allows our group to continuously monitor the spatial and vertical distribution of zooplankton and fish, the later mostly represented by Arctic cod (*Boreogadus saida*). The hull-mounted transducers are in operation 24h a day and will provide an extensive mapping of where the fishes are within the region of interest over a yearly cycle.

General Recommendations:

Some of our samples kept in one of the outdoor freezer (-20°C, starboard side) thawed for and unknown reason and an undetermined period of time. Keep an eye on that. The cold room in the zooplankton van had some difficulties to keep a stable temperature during leg 8a but seems to be working fine now. If you intend to use it, we suggest to monitor the temperature for 2-3 days before. For an unknown reason, the lab incubator also had a warming episode (up to 16°C) despite regular defrosts and no door opening (that happened early in the morning before anybody had come to the lab for that day). Keep an eye on that as well. In short, watch all temperature controls all the time!!!

This leg was a lot of work for only two people considering that: 1) the time-consuming measurements/conservation of the numerous Arctic cod larvae caught during the last 4 weeks of the leg, 2) the inexperience of the participants regarding some of the sampling methods and experiments, 3) the preparation work for the beginning of the foredeck sampling with the Monster and the Tucker nets. We did our best and hope everybody will be satisfied with the samples collected and experiments conducted. However, some variety in sampling activities (moonpool, ice, foredeck) prevented the work from becoming too monotonous. Otherwise, hockey game, ridge expedition and diving hole digging also entertained us. We would like to thank the captain and crew, chief scientists and all the people who helped us in any way during the leg, especially Steeve, Benoit and Roger (the three stars of the leg), Claire and Dan (the filtered water furnishers), Alexis, Joanne and Christian (the net helpers).

2.5. Team 6

PIs: Tim Papakyriakou (U of M), Lisa Miller (IOS) and Jean-Louis Tison (Ulb – Belgium), Helmuth Thomas (Dalhousie)

Participants: Will Drennan (U.Miami-RSMAS), Jens Ehn (U of M), Nicolas-Xavier Geilfus (Ulb – Belgium), Keith Johnson (IOS), Doris Leong (Dalhousie), Friederike Prowe (Dalhousie)

Overview

The main goal of Team 6 is to investigate the sea-ice-atmosphere exchanges of climatically active gases (such as carbon dioxide and dimethyl sulfide). Gas concentrations and near-surface fluxes are measured from installations on the ship and from the sea ice. In order to better understand the driving factors regulating those exchanges, we are looking at ice and water biogeochemistry, selecting a set of variables that describes the best ice and water column conditions in terms of physical, biological and

chemical properties. Meteorological and surface climatological data are also collected to relate the observed fluxes and ice/ocean properties to near-surface microenvironment. Collectively this information should provide a good description of the gas cycles and their dynamics in the arctic environment of the flaw lead system over the annual cycle.

Sampling and deployments were undertaken as part of CFL Drift Mode – where the ship would associate itself with an ice floe or landfast ice for a period of time ranging from a few hours to about a week. On leg 8, a number of days of open water transects were also conducted. Our sampling, monitoring and the associated data set is described in the following sections.

2.5.1. Surface Meteorology and Flux Project

Introduction

The surface meteorology and flux program (CFL Team 6) is designed to record basic meteorological conditions and to study exchanges of momentum, heat and mass across the atmosphere-sea ice-ocean interface. The main value of this program to the overarching objectives of Team 6 is the direct measurement of CO_2 fluxes and measures of the basic terms of the heat budget (sensible and latent heat, radiation fields).

Turbulent fluxes (CO_2, heat and momentum) are measured by the eddy covariance technique, which is dependent only on atmospheric measurements. To realize the potential of the data set the measurements of the CO_2 flux, in particular, require ancillary information on processes (physical, biological and chemical) that drive gas exchange. In an open-ocean situation this context is largely provided by measurement of sea-surface pCO_2, but the situation becomes much more complex when a sea ice cover is included in the equation. Surface flux monitoring facilities are deployed on the ship`s foredeck, and when possible, on the sea ice.

This section of the CFL Team 6 cruise report reviews the atmospheric and sea surface pCO_2 measurements that were made during Leg 8. Other sections of the report will deal with the sea ice measurements that were made in support of the CO_2 flux measurements.

Ship-Based Micrometeorology and Eddy Covariance Flux Tower

The micrometeorological tower located on the front deck of the Amundsen (Figure 1) provided a continuous record of meteorological variables and eddy covariance parameters. The setup on leg 8 was kept unchanged from the previous leg. A number of slow response sensors were installed on the tower that recorded bulk meteorological variables (i.e., air temperature, humidity, wind speed/direction, skin surface temperature). Other fast response sensors recorded the eddy covariance parameters (i.e., CO_2/H_2O concentration, 3D wind velocity, 3D ship motion, and air temperature) (Table 1). In addition, radiation sensors (Figure 1, Table 1) were installed on the roof of the wheelhouse to provide information on incoming radiation fields, including: long-wave, short-wave, photosynethetically active radiation (PAR), and ultra-violet radiation (UVA and UVB). All data was logged to Campbell Scientific dataloggers; a model CR5000 logger was used for the eddy covariance data, a CR1000 logger for general meteorological elements (e.g., temperature, relative humidity, etc.), and a CR23X for the radiation data. All loggers were synchronized to UTC time using the ship's GPS system as a reference.

The eddy covariance system on the tower makes use of two separate gas analyzers and a single 3D sonic anemometer. The dual gas analyzers system allows us to make use of both closed path and open path eddy covariance systems. The open path gas analyzer has the benefit of making measurements concurrently with the sonic anemometer, but the closed path gas analyzer is not as easily disturbed by adverse weather conditions.

In order to make sure that the two systems are comparable, careful calibrations were performed on both instruments. The closed path system is based on a LI-7000 gas analyzer which employs two optical cells, one of which was used to monitor the drift of the instrument by constantly passing a stream of ultra-high purity N_2. In addition, the sample cell of the instrument was calibrated daily using the ultra-high purity N_2 to zero the CO_2 and H_2O measurements, and a reference gas of known CO_2 to span the instrument. Occasionally, a span calibration of the H_2O sensor was performed using a dew point generator (model LI-610). The open path gas analyzer (LI-7500) could not be calibrated as conveniently, and so it was calibrated once at the end of the leg. In general, we find that this is effective for this particular instrument, which does not drift significantly over time.

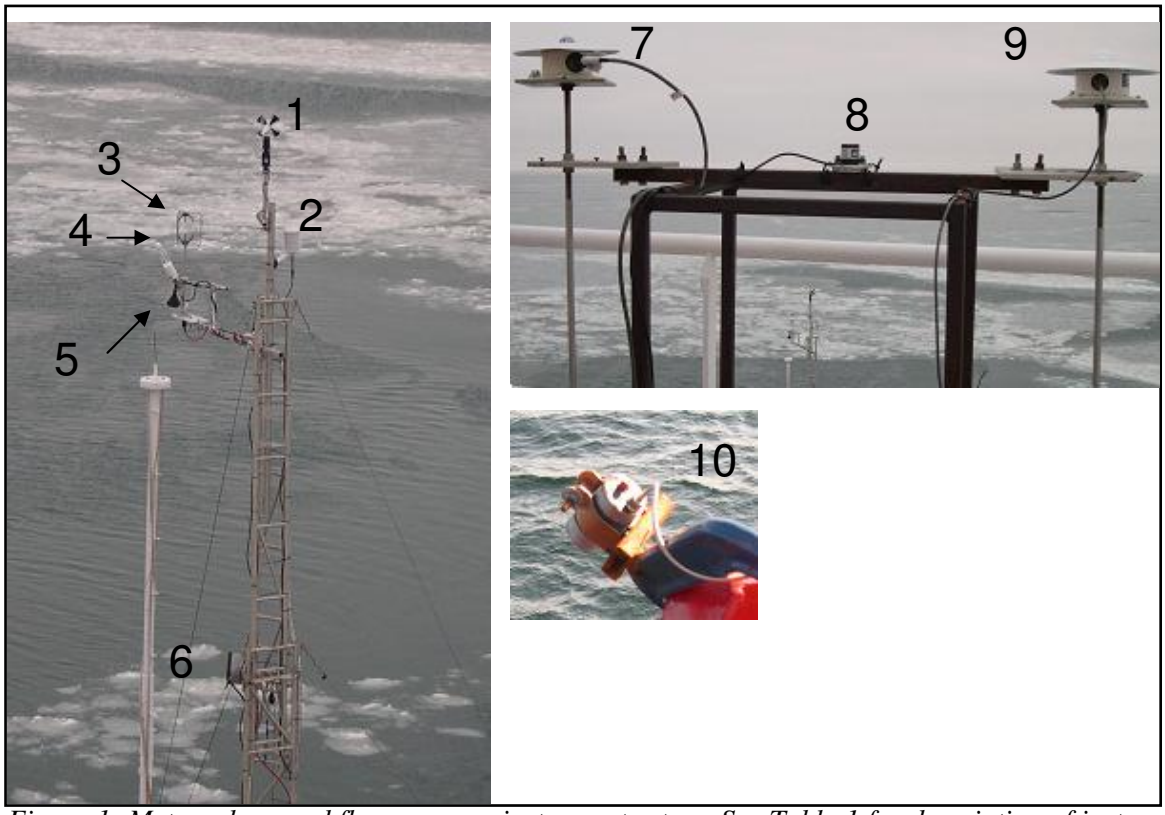

Figure 1: Meteorology and flux program instrument setup. See Table 1 for description of instruments based on the numbers. Note that on Nov. 18 the Motion Pak (6) was moved to the rear face of the tower to facilitate easier motion correction, and the UV sensor is not shown.

The meteorological tower at the bow of the ship ran consistently for the duration of the leg with the exception of occasional periods when the LI-7500 and Gill sonic anemometer were inoperable because of ice and frost build-up. This often happened especially during night-time when temperatures generally were colder and there was less radiative heating of sensors. During daytime, the instruments were typically in good conditions except for a few days when rainy and/or foggy weather conditions lead to moisture or ice build-up. The sensors and other instrumentation shown in Fig. 1 were checked and maintained every morning around 7am. A daily log of these activities was kept in a notebook. Atmospheric CO_2 data is shown together with seawater pCO_2 data for a few days in Figure 5. The extent of data lost due to atmospheric conditions cannot be estimated at this time, and will only be known once post processing is complete.

Ice-Based Micrometeorology and Eddy Covariance Flux Tower

An ice-installation (Fig. 2) was installed on June 2 in Darnley Bay (a few days prior to the leg 9 crew change). The meteorology and flux instruments were installed on a 4.5m long tower section of a TV antenna-style (Fig. 2). A list of variables that were monitored is shown in Table 2. The installation was powered by lead-acid batteries (12 VDC), which themselves were trickle charged when necessary by a battery charger and a generator (which was then placed 30-40m upwind of the tower). The vertical ice temperature profile was monitored by thermocouples arranged in profile within a white PVC tube. Signals associated with the set-up logged by a Campbell Scientific loggers: model CR1000 for basic meteorology and temperature, and model CR3000 for the components of the eddy covariance system. Raw data from the flux sensors were sampled at 20Hz and immediately transferred to flash card. The closed path LI7000 system was not installed at the time. The LI-7500 was calibrated onboard the ship prior to deployment.

Meltponds had formed on the ice at the time of installation. Meltpond coverage was visually estimated to be about 60% of the surface. In the morning the ponds were covered by a thin (1-2cm) ice layer that could be walked upon. This ice layer was gradually deteriorating during the day. The tower was installed on a mound that had a white appearance roughly 400 m south of the ship. The ice thickness was about 1.8m and the snow cover had already melted away.

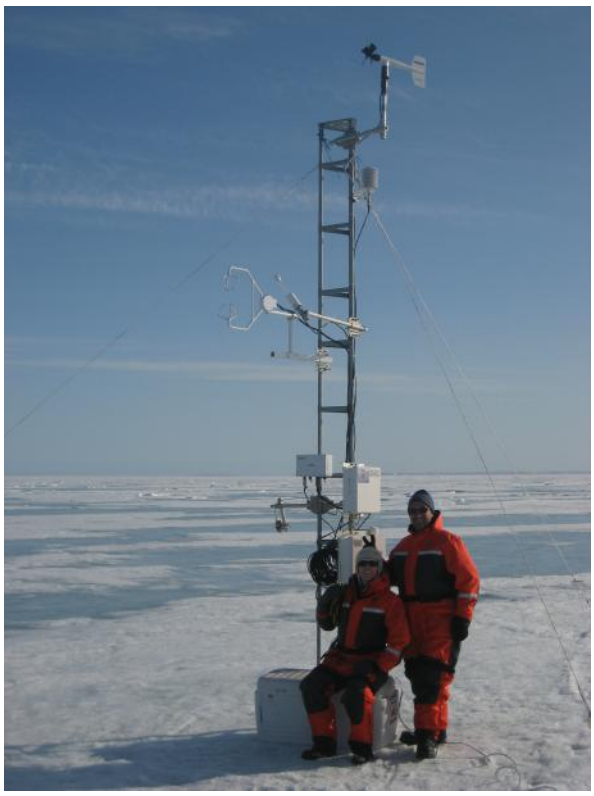

Figure 2: Meteorology and flux instrument setup on sea ice in Darnley Bay. See Table 1.2 for description of instruments that were installed. The cooler contains the 12VDC power supply.

Table 2: Description of instruments shown in Fig. 1.4 (going from the top).

On-track pCO2 System

Methods

A custom-built pCO_2 system was utilized on this leg to measure dissolved CO_2 in the surface layer of the seawater in near real time. The system is located in the engine room of the Amundsen (Figure 4). It draws sample water from the ship's clean water intake. The water is passed into a sealed container through a shower head, maintaining a constant headspace. This set-up allows the air in the headspace to come into equilibrium with the CO_2 concentration of the seawater. The air is then cycled from the container into the LI-7000 gas analyzer in a closed loop. Thermocouples were used to measure water temperature immediately before entering the equilibration chamber, and to measure the temperature of the air in the chamber. All data were logged to a Campbell Scientific CR3000 datalogger.

As on the leg before, the LI-7000 gas analyzer was calibrated daily using ultra-high purity N_2 as a zero gas, and a gas with known CO_2 concentration as a span gas. Furthermore note that the other LI7000 closed path system located at the tower on foredeck, measuring the pCO_2 of the air, was also calibrated daily, allowing for an estimation of the CO_2 flux between air and seawater. Spanning of the H_2O sensor was not necessary because a desiccant column removes H_2O from the air stream before passing into the sample cell. The desiccant was changed roughly every 1-2 weeks when pH_2O levels 6-7 ppm. As with the foredeck closed path system, a stream of N_2 is constantly cycled through the reference cell of the LI-7000 to monitor and correct for drift of the instrument.

Figure 4: The on-track pCO_2 system located in the engine room of the Amundsen. The equilibration chamber is the clear cylinder. Seawater is filtered in the blue cylinder before entering the chamber. The gas analyzer is the box with the digital display. To the right of it, the container of desiccant is seen. The tanks with N_2 and CO_2 are seen in the foreground.

Sample Data

Figure 5 shows an example of a few days of CO_2 data recorded by the on-track system, along with water temperature. During 2-3 June the ship was in Darnley Bay, and the data can be compared with ice station data (Figure 3). However, further processing must still be undertaken to correct the values for changes in temperature that occur due to the length of the sample line (see section 2.4.3), and to properly calculate pCO_2.

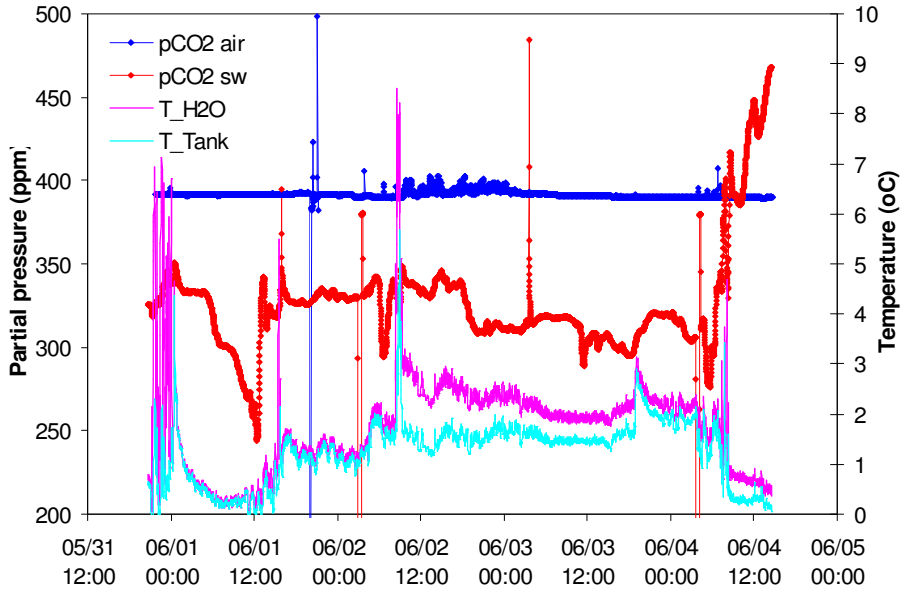

Figure 5: Sample on-track pCO_2 in air and in the seawater. The temperatures of the incoming seawater and the seawater in the tank is also shown.

Temperature corrections

On 27-May (0506 UTC) a water sample from the intake (near junction point for equilibrator source) was drawn for TA/DIC analysis. pCO2 was found to be 274ppm, compared to 315ppm from the equilibrator. To determine how much of the difference was a temperature effect, on 2 June (0200-0230) we lowered a CTD over the side of the vessel to measure temperature at intake depth (estimated by Steeve to be 5m). A profile to 5m on the port side near the intake position was halted after the CTD drifted below the vessel (there was little wind or waves). A second CTD was carried out near the bow on the STB side. Here, the CTD was lowered to 14m, with 30sec stops at each 1m. In addition, a bucket temperature sample at the intake was made. In Fig 1.8, we plot the CTD temperature profile, along with intake temperature and average values (0215-0230) of temperature from the TSG and pCO2 system "Tank_Temp_Avg". The pCO2 system "H2O_T_Avg"was about 0.12C higher than Tank_Temp_Avg, and is not shown.In summary, assuming a 5m intake depth, the intake bucket temperature is 0.1C warmer than T_water, the TSG temperature is 0.45C warmer and the equilibrator tank temperature in 1.9C warmer. Given a solubility effect of about 4%/deg (need to check this), the 1.9C increase can account for a 25ppm change in pCO2, over half that observed.

A comparison was also made between pCO2 values from the U of M equilibrator system and the SIES unit. On 1-June (2230), the SIES unit was plumbed into the seawater intake. By 2330, a steady value of 708ppm was registered. A CO2 gas span of 379.403 yielded 793ppm (at 2345). A subsequent N2 zero yielded 356ppm, giving a linear curve for the SIES unit as pCO2 = 0.868 * (out – 356). A reading of 708 is equivalent to 305ppm, compared to 333ppm (between 331-334 during 2230-2315) recorded on the U of M equilibrator. This difference of 18ppm is close to that expected based on the 1.8 deg difference between intake and equilibrator temperatures noted above.

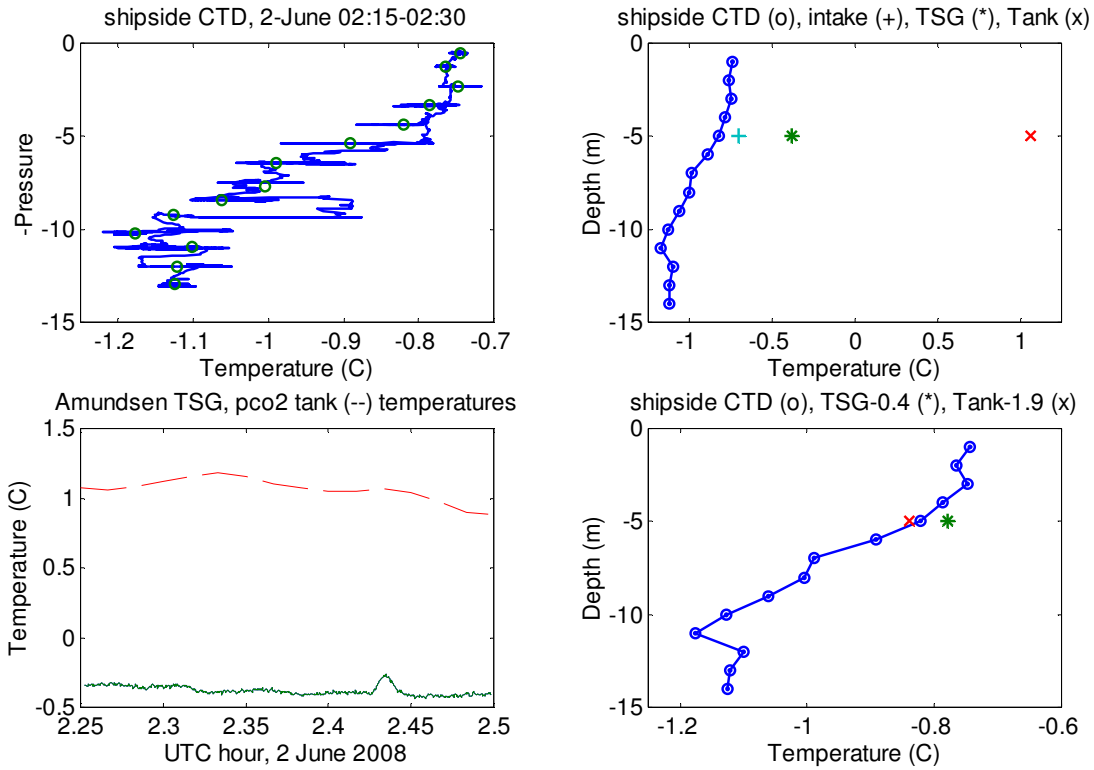

Figure 6: Temperature off set experiments of 2-June 02:00-02:30.Upper left: Temperature versus depth from CTD, where the green circles show means at each depth. Upper right: Temperature vs depth showing CTD means (o),bucket intakeat 0150 (+), TSG mean(*) and equilibratortank mean(x). Lower left: Time series of TSG and equilibrator tank temperatures during CTD. Lower right, as above with offset corrections for TSG and tank temperatures.

2.5.2. Sea Ice Biogeochemistry

In-Situ measurements and Ice Core Collection

In order to get a set of biogeochemical variables that will help us understand the dynamics of processes happening in sea ice and seawater, we collected ice cores for further analysis in both Winnipeg, Brussels and Liege labs. Basically, we took between 10 and 12 cores at each station. A major concern throughout the whole sampling procedure has been to prevent contamination of trace metal samples, especially iron. We followed the trace metal clean procedures proposed by Lannuzel et al. 2007. Nitrile gloves were used for handling the iron dedicated samples, and items used for sample collection and storage were acid-cleaned and sealed in plastic bags. The electropolished stainless steel core barrel (Lichtert Industries, Brussels, Belgium) has been specially designed and tested to be non-contaminant for iron. Seawater was pumped up with a portable peristaltic pump (Cole-Parmer, Masterflex E/P). Finally, the sea ice cores dedicated to iron determination were immediately packed in cleaned plastic bags and stored at minus 25 degrees Celsius.

Additionally, we measured a couple of standard variables in the field (e.g.: freeboard, snow thickness, snow temperature...). A complete list of the variables that will be accessible for the leg 8 is presented in Table 3.

Table 3: Summary of variables collected from snow/sea ice/brine/seawater samples

Brine and Seawater Samples

Sampling of brine from the sea ice was conducted by drilling shallow sackholes (ranging from 20 cm down to almost full ice thickness) through the surface of the ice sheet. The brine from adjacent brine channel and pockets was allowed to seep into the sackhole for 15-120 min (depending on ice temperature), with the hole covered with a plastic lid (Gleitz et al., 1995), reportedly the best current method to sample brines for chemical studies (Papadimitriou et al., 2004). Brine and sea water were pumped from the hole using a peristaltic pump (Masterflex® - Environmental Sampler).
Samples for alkalinity (TA), dissolved inorganic carbon (DIC), chlorophyll (chl), pCO_2, temperature, salinity, O^{18}, and DMS were taken.

Analysis for DIC and TA was performed using the VINDTA 3C (Versatile Instrument for the Determination of Titration Alkalinity) developed by Marianda (see section 4).
Chlorophyll, temperature and salinity are also measuring immediately onboard (AO).
The samples for O^{18} and DMS will be sent back to Brussels and analyzed.

The pCO2 was measured directly on the field using the Sea Ice Equilibrator System (SIES). This device allows measurement of pCO_2 by utilizing a membrane contractor equilibrator (Membrana® Liqui-cell) coupled to an infrared gas analyzer (IRGA, Li-Cor® 6262). All instrumentation of the SIES unit were enclosed in an insulated box that contained a 12V power source and was warmed to keep the inside temperature just above 0°C. Seawater flow through the equilibrator at a rate of 1 L min-1 and a closed air loop ensures circulation through the equilibrator and the IRGA at a rate of 3 L min-1. Temperatures were measured in situ simultaneously in the brine sackhole and at the outlet of the SIES unit. A temperature correction of the pCO_2 was applied assuming that the relation from Copin-Montégut (1988) is valid at low temperatures and high salinities. The IRGA was calibrated using CO_2-in-air standards with mixing rations of 0 ppm and 369.4 ppm of CO_2 supplied by Air Liquide Belgium® shortly after returning to the ship (while the IRGA was still cold). Stable field pCO_2 readings could take considerable time to obtain (up to 1 hour from turning on the flow of gas) especially when pCO_2 values were low in the brine.

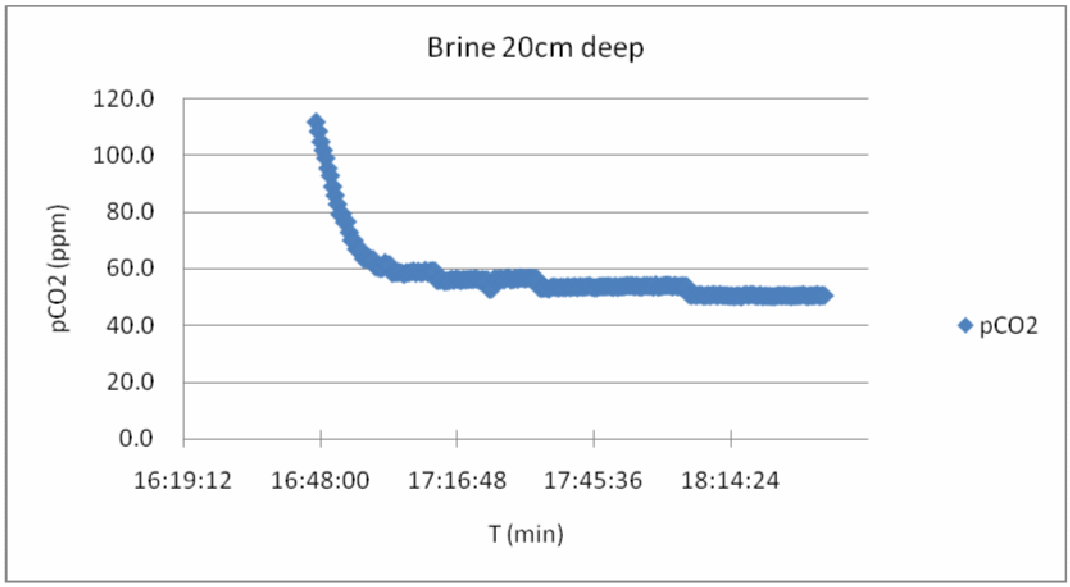

Figure 7: Equilibriation of pCO_2 of brine in the SIES unit at station F6.

Gas chamber measurements

A chamber coupled to the SIES was used to measure air-ice CO_2 fluxes. The accumulation chamber (West system®) is a metal cylinder closed at the top (internal diameter 20 cm; internal height 9.7 cm). A rubber seal surrounded by a serrated-edge iron ring ensured an air-tight connection between the base of the chamber and the ice. For measurement over snow, an iron tube was mounted at the base of the chamber to enclose the sampled snow down to the ice and to prevent lateral advection of air through the snow. The chamber was connected in a closed loop between the air pump (3 L min^{-1}) and the IRGA of the SIES. The measurement of pCO_2 in the chamber was recorded every 30 sec for at least 10 min. The flux was computed from the slope of the linear regression of pCO_2 against time ($r^2 \geq$~ 0.99) according to Frankignoulle (1988). The uncertainty of the flux computation due to the standard error on the regression slope is on average ±3%. CO_2 fluxes values correspond to the average of three measurements. The idea is to look at the changes in the pCO_2 between the beginning and the end of the gas chamber deployment. Any increase in this pCO_2 can then be understood as a positive flux from the ice – any decrease as a negative flux.

We did several gas chamber measurements during the main coring stations but also during small punctual stations. In order to investigate the influence of the ice properties on the fluxes, we put the chamber on different ice types and thicknesses.

Figure 8: Measurement of fluxes on drift station D44 (09/04/2008)

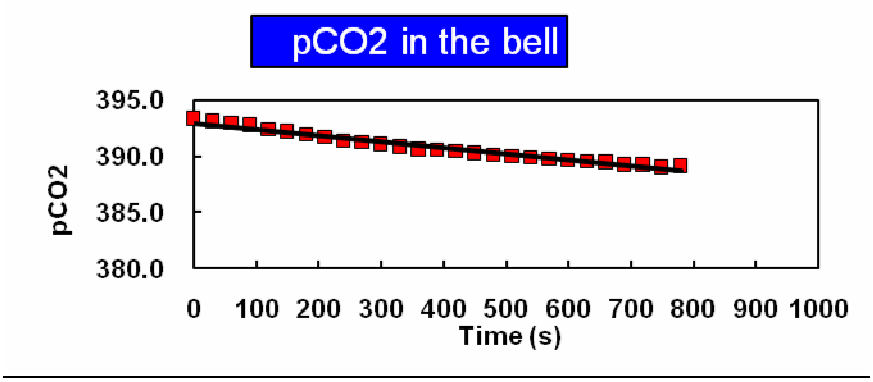

Figure 9: Bell (chamber) measurements on the last ice station of the leg (Darnley Bay; F6) showing a CO_2 flux down into the ice. At the time, on the last ice station, on the top of the ice wit melting point.

Ice Cores

All the ice cores are stored in a freezer container onboard.

On the field the temperature of the ice is taking directly after the extraction of the ice core. After, on the same ice core we cut it each 5 cm to measure salinity but also chlorophyll, and to take samples for O^{18}. Towards the end of the leg, when the sea ice was warm and significant brine drainage occurred after sample removal from the core hole, ice cores were cut into 5cm segments and placed in buckets immediately in the field.

Onboard, the ice core Cs3 was melted in a cold room at +4°C for the study of minerals of $CaCO_3$ and ikaite. The melt water was filtrated on a GF/F and the filter was stored in the freezer container for further analysis back in Belgium.

2.5.3. Dissolved Inorganic Carbon (DIC)/Alkalinity Project

PI: Helmuth Thomas, helmuth.thomas@dal.ca, Department of Oceanography, Dalhousie University, Halifax, NS, Canada;
Participants: Doris Leong, 24.04.-15.05.2008 (doris.leong@dal.ca, Department of Oceanography, Dalhousie University, Halifax, NS, Canada); Friederike Prowe, 15.05.-05.06.2008 (fprowe@ifm-geomar.de, now at: Marine Biogeochemistry, IFM-GEOMAR Leibniz Institute of Marine Sciences of the University of Kiel, Kiel, Germany)
submitted by Friederike Prowe

The ocean's exchange of carbon dioxide with the atmosphere is governed by the biogeochemical cycling of carbon and physical processes throughout the water column, which determine the concentration of dissolved inorganic carbon in the surface waters. Of the seven relevant carbon system parameters, a minimum of two are needed to calculate the others and fully describe inorganic carbon chemistry, overdetermination of the system being beneficial. During CFL leg 8, seawater, brine and ice core samples were taken analyzed for dissolved inorganic carbon (DIC) and total alkalinity (TA), yielding two relevant parameters. Due to the high work load, unfortunately pH could not be determined. Parallel to seawater and brine for DIC and TA, samples were taken for d13C, preserved and stored for later analysis.

DIC and TA in the water column

500 ml water samples were collected in glass bottles from the rosette at several depths for determination of DIC and TA. Sampling was performed according to protocol SOP1 (Dickson et al, 2007). Samples were usually first to be taken from the niskin bottles, or preceded only by dissolved oxygen at individual casts and depths. Since the contaminants group was analyzing for mercury, samples were only preserved using 200 µl saturated solution of $HgCl_2$ to inhibit biological processes if they could not be analyzed within 24 hours of sampling. Spiking took place in the lab after sampling at the rosette had been completed, and samples were stored in the dark at room temperature until analysis, since no space was available to keep samples at 4°C.

30 ml brown glass bottles were filled according to the same sampling protocol as for DIC/TA, and in the lab preserved with 30 µl saturated solution of $HgCl_2$. Bottles were sealed with parafilm and stored in the dark at room temperature, until at 27.05.2008 space could be found to keep them at 4°C from then on.

DIC and TA in sea ice, brines and under-ice water

Brine was taken from sack holes at several depths per ice station, depending on ice thickness and temperature, and filled into 500 ml glass bottles using a peristaltic pump (see section 3.2). When only low volumes of brine formed, e.g. for shallow depths, 250 ml bottles were used instead. At the same time, seawater from the ice-water interface and from 1 m below the interface was taken. Upon return to the lab, samples were preserved with saturated solution of $HgCl_2$, and kept in the dark at room temperature until analysis. Temperature was measured in-situ, and salinity later measured in the lab.

Similar to seawater samples, 30 ml bottles were filled for d13C, preserved, sealed and stored in the dark at room temperature/4°C.

At ice stations, one ice core was drilled specifically for DIC/TA and 15 cm sections from top, bottom and the middle of the core put into gas inpermeable Tedlar bags with a valve for removing gas or liquid. The bags were closed with a clamp type seal, and surplus air removed through the valve using a nalgene hand pump. At the lab, 200 µl saturated solution of $HgCl_2$ was added through the valve, and the samples left to melt in the dark.

DIC and TA analysis

DIC and TA were analyzed on board using a VINDTA 3C (Versatile Instrument for the Determination of Titration Alkalinity) by marianda. Prior to analysis, samples were heated to 25°C in the lab and using a circulation water bath. TA was determined by titrating a volumetrically accurate subsample using 0.1 M HCl as titrant, and a set of three electrodes, a Ross pH electrode, a reference AgCl electrode and an auxiliary platinum electrode.

Seawater samples were analyzed using a total volume of 4.2 ml titrant at dosage steps of 0.15 ml. For brine samples with higher salinity and alkalinity, total volume and dosage were adjusted to 14.7 ml and 0.3 ml, respectively. These parameters were not adjusted to the individual salinity/alkalinity of every brine sample, but kept constant for the entire batch for reasons of comparability. Possibly due to this procedure, the latter method appeared to result in less accurate values because it involved greater errors in the fitting procedures applied to determine TA over the comparatively wide range of salinities found in the brines. Subsequent reevaluation of the titration data can probably reduce the involved deviations and lead to more consistent results.

For measuring DIC, a volumetrically determined subsample was acidified with 8.5% H_3PO_4 to convert all inorganic carbon into gaseous CO_2. The CO_2 was stripped out of the sample using ultra-pure N_2 gas, transferred into a coulometric titration cell and detected using the coulometric method (Johnson et al., 1993).

Ice core samples had not been analyzed until the end of the leg, and were kept for further onboard analysis in the following weeks.

Seawater standards (Certified reference material, CRM, batch 81, provided by Prof. Andrew Dickson, Scripps Institution of Oceanography, La Jolla, CA) were used to calibrate the DIC and TA data and ensure quality control. Samples were run in batches of 25-30 bottles on one coulometer cell, with a standard at the beginning and the end of the day.

Barium in the water column

In the Canadian Arctic, barium (Ba) is mainly released from the North American continent and can therefore be used as a tracer for terrestrial freshwater input. Together with ^{18}O, a tracer for freshwater input from precipitation and ice melt, all freshwater sources to the Arctic can be quantified.

Samples for barium were taken from the rosette parallel to samples for ^{18}O, at approximate depths 5, 10, 25, 50, 75, 100, 150, 200 and 500 m. 15 ml nalgene bottles were rinsed three times, then filled and back at the lab spiked with 15 µl concentrated HCl. Sample bottles were sealed with parafilm and stored in the dark at 4°C until taken for later analysis using isotope dilution mass spectrometry.

2.5.4. Laser Wave System (LAWAS) Project

The University of Miami LAWAS consists of 4 Riegl LD90-3 laser altimeters mounted in a square array of 0.3m diameter. LAWAS is mounted on a boom near the bow on the port side (see Fig. 8.1). A Systron Donner MotionPak is mounted at the center of the array to measure all six components of motion of the laser array.

Fig. 8.1 Photographs showing LAWAS position near bow of Amundsen.

The LAWAS system is designed to measure time series of wave slope in two directions, from which rms slope of the sea surface can be calculated. Of particular interest are measurements coincident with Quiksat overpasses. Typically six overpasses occur each day, between 01 – 13 UTC. The project objective is to relate CO2 gas transfer to Quikscat derived backscatter measurements. LAWAS deployments took place on May 18 (2129-2233), May 20 (0155-0315), May 22 (0220-0520), May 24 (0015-1315, multiple runs), May 26 (1958) almost continuously until May 28 (0524).

2.6. Team 7

2.6.1. Carbon & nutrient fluxes

PI: Jean-Éric Tremblay (Department of Biology, Laval University)

Participants: Jonathan Gagnon, Johannie Martin, Simon Pineault, Kyle Simpson (Department of Biology, Laval University)

Rationale. The Arctic climate displays high inter-annual variability and decadal oscillations that modulate growth conditions for marine primary producers. Much deeper perturbations recently became evident in conjunction with globally rising CO_2 levels and temperatures (ACIA 2004; Comiso 2003). The thickness and extent of Arctic sea-ice decrease rapidly (Johannessen et al. 1999; Rothrock et al. 1999) and the ice-free season is extending both in the Arctic (Laxon et al. 2003) and subarctic (Stabeno & Overland 2001). Models predict further reductions in ice cover (ACIA 2004). These changes entail a greater penetration of light into surface waters, which is expected to bolster phytoplankton production (Rysgaard et al. 1999), food web productivity and CO_2 drawdown by the ocean. At present, phytoplankton production varies by two orders of magnitude across the Canadian Arctic, but the forcing mechanisms are poorly understood and quantified. In the Canadian Archipelago, the productivity of phytoplankton is likely to be limited by light or the supply of allochtonous nitrogen, depending on ice conditions. The supply of allochtonous nitrogen is influenced by climate-driven processes, mainly the large-scale circulation, river discharge, upwelling and regional mixing processes. Over most of the western Arctic, and especially the Beaufort Sea, the concentrations of inorganic nitrogen (i.e. nitrate, nitrite and ammonia) at surface remain low throughout the year and the phytoplankton possibly depend on local recycling and the dissolved organic nitrogen (DON; e.g. urea, amino acids and primary amines) supplied by rivers. A large portion of the phytoplankton biomass is typically located within subsurface chlorophyll maxima (SCM). SCM productivity is possibly in balance with the episodic supply of nitrate across the halocline and/or the supply of ammonium and nitrate by local recycling and nitrification, respectively. Despite the importance of SCM for the food web and CO_2 fluxes, little is known about their structure, turnover and susceptibility to environmental variability and change.

Objectives. The main goals of our team for leg 8 of ArcticNet 2007&CFL were to **(1)** establish the horizontal and vertical distributions of phytoplankton nutrients and the influence of different processes (e.g. mixing, upwelling and biological processes) on these distributions, **(2)** characterize the detailed vertical structure of chlorophyll-*a* with respect to irradiance, nutrient supply and physical structure, **(3)** experimentally assess causal relationships between phytoplankton productivity and the availability of light **(4)** determine the utilisation of different sources of inorganic and organic nitrogen by phytoplankton, and **(5)** assessed the role of the ice algae during the initiation of the primary production in the water column. Ancillary objectives were to calibrate the *SeaPoint* fluorometer and *ISUS* nitrate probe attached to the Rosette.

Methods. Samples for inorganic nutrients (ammonium, nitrite, nitrate, orthophosphate and orthosilicic acid) and urea were taken at all rosette stations (see Table 1) to establish detailed vertical profiles. Ammonium was determined immediately after collection using modifications of the manual fluorometric method (e.g. Holmes et al. 1999). Urea samples were either frozen or analyzed fresh using the method of Mulveena & Savidge 1992. The concentrations of nitrate, nitrite, orthophosphate and orthosilicic acid were determined on fresh samples using an Autoanalyzer 3 (Bran+Luebbe) with colorimetric methods adapted from Grasshof (1999).

Samples for the natural abundance (Table 1) of ^{15}N and ^{13}C in particulate organic matter were taken from ice-core (bottom part; 2 to 4 cm), ice-water interface, at 5 m and at the chlorophyll maximum (30 m if no maximum were observed). Volumes ranging from few millilitres (for ice samples) to 12 to 20 litres (for water samples) were filtered onto 24 or 47 mm pre-combusted GF/F filters and the filters were desiccated at 60°C in a drying oven. These data will be used for nitrogen uptake calculations and to assess the nitrogen status of phytoplankton communities.

The relationship between light and the uptake of C and N by phytoplankton (light-gradient incubation in Table 1) from the chlorophyll maximum was assessed using dual labelling with stable isotopes of C and N in four light-gradient modules (10 light intensities). Temperature was maintained at *in situ* levels with a chilling circulator. Samples from all modules were spiked with ^{13}C-bicarbonate; two modules received saturating additions of ^{15}N-nitrate, ^{15}N-ammonium (or ^{15}N-urea, or ^{15}N-nitrite), and the other two trace additions. Incubations were terminated by filtration onto 24-mm GF/F filters. All

filters were desiccated at 60°C and stored dry for post-cruise determination of isotopic enrichment and particulate organic carbon and nitrogen.

SetCol protocol (Bienfang 1981) was carried with water from ice-core, ice-water interface and chlorophyll maximum (or 30 m) at the stations where ice was sampled or incubations were performed to measure the sinking rate of the micro algae cells. Fractions from the top, the middle and the bottom part of the column were filtered on GF/F filter and extracted with acetone to determine the chlorophyll concentrations. Samples for the taxa composition were taken in the top, the middle and the bottom fraction in a second column and were stored with acid lugol for a post-cruise analysis.

The size partitioning of ice algae was execute by filtering melted core on 200 µm and 20 µm filters (to obtained the isotopic signature of the different organisms) at same station that natural abundance analysis. The effects of incubation treatments (variable nutrient additions and light conditions) on the photosynthetic characteristics of phytoplankton were assessed by Pulse Amplitude Modulated fluorometry (PAM; Heinz-Walz). Nitrate data were used to calibrate the ISUS nitrate probe. Calibration of the Rosette fluorometer was achieved by comparing the instrument's output with extracted chlorophyll *a* and PAM data. The Phytoflash system, powered by a CTD (SBE-19), was deployed in self-contained mode from the front deck to obtained *in situ* photosynthetic yield in the water column.

Subproject: Pathways of cycling and export of organic material in the sea ice and flaw lead system.

The overall objective of this project is to further our understanding of the cycling and downward export of organic material in the sea ice, at the ice-water interface, and in the flaw lead system. Sea ice contains a diverse community of organisms which is integral to the cycling of organic matter in the Arctic Ocean. Microorganisms are incorporated into the sea ice during periods of ice formation (Riedel et al. 2007). During the spring, there is a conspicuous ice algal bloom which develops in response to increasing light availability. Sea-ice production is coupled with both pelagic and benthic production (e.g. Michel et al. 1996, Renaud et al. 2007) and may contribute 25% or more to total Arctic primary production (Legendre et al. 1992, Gosselin et al. 1997). The objective for the seventh leg of the CFL system study was to investigate sea-ice organic carbon pools. This research will provide a better understanding of annual cycles of sea-ice carbon cycling in relation to exopolymeric substances (EPS) as well as physical sea-ice characteristics (Light, snow, ice).

Sample collection
Sea ice
Sea-ice associated samples collected during Leg 8 are summarized in Table 1. Complete ice cores were collected to obtain vertical profiles of the variables listed in Table 2, including nutrients and dissolved organic carbon (DOC) profiles. The ice sections for the vertical profiles were melted in sterile Whirl-Pak bags without the addition of filtered sea water. The cores were cut into 10 cm sections, except for the bottom section (nearest the water) which was cut into a 0 to 3 cm and 3 to 10 cm section. Three complete cores were collected on each sampling day and the corresponding sections were combined to obtain enough volume for all analyses.

Bottom ice samples (0-3 cm and 3-10 cm sections only) were also collected to measure spatial variability of bottom ice. A triangular sampling plan was used to assess the variability of all variables at 5, 3 and 1.5 m scales. We wanted to determine if there was detectable spatial variation in sea-ice constituents that could be linked to snow cover variability in the winter. Such variability could possibly be related to different rates of ice growth linked to the insulating properties of snow cover. The samples were melted with the addition of filtered seawater (0.2 µm polycarbonate membrane filters) to minimize osmotic stress during the melting process (Garrison & Buck 1986). Again 3 cores were combined to obtain enough volume for the analyses (Table 2). All ice cores were collected with a manual ice corer (Mark II coring system, 9 cm internal diameter, Kovacs Enterprise). With each ice collection we measured the freeboard and ice and snow thickness.

Surface water
On the majority of ice sampling days interface and 1m water samples were collected (Table 1). The water was collected from the ice-water interface using an under-ice arm and pump. This water was analyzed as described in Table 2 and a portion was filtered for the melting of the bottom ice samples.

Partial ice cores were removed to make sac holes into which brine could drain. The brine holes were covered with Styrofoam plugs and left to drain for 24 h before the brine was collected with a sterile syringe. A minimum of 10 cm of ice remained in all brine holes to limit the infusion of surface water.

Table 1. Summary of sea-ice associated sampling conducting during Leg 8.

			Samples collected

Under-ice sediment traps
Short-term particle interceptor traps (sediment traps) were deployed at 1 m, 15m, 25m and 50m from the bottom of the ice. The traps were deployed for 3-4 day periods to collect sinking organic matter.
The sediment traps were PVC cylinders with an internal diameter of 10 cm and a height/diameter ratio of 7. Before each deployment, deep water (>150 m) was collected and filtered through a 0.2 µm polycarbonate membrane filter. The traps were filled with the filtered deep water so that the trap water would be denser than the surface waters in which the traps were deployed. Prior to deployment, the filtered seawater was analyzed for DOC, salinity, conductivity and temperature. Upon recovery of the traps, the total volume (~5.6 L) was used to assess DOC and total chl *a* concentrations. Salinity, conductivity and temperature were again measured. Cell samples were also collected for fecal pellet (microscopic counts) and bacterial (flow cytometry) abundances as well as cell taxonomy (preserved with acidic lugols). Exopolymeric substances (EPS) were measured to assess their association with sinking material.

Table 2. Summary of sediment trap deployments CFL Leg 8.

Sample analyses

The variables assessed for the ice associated samples are summarized in Table 2. The methods used for these analyses are briefly described below.

Table 4. Summary of variables analyzed for sea-ice, surface water and under-ice sediment trap samples during leg 8 of CFL.

	Ice profile	Sea-ice spatial survey (Bottom Ice)	Surface water	Under-ice trap
Salinity	X	X	x	x
Conductivity	X	X	x	x
Temperature	X	X	x	x
Total Dissolved Solids	X	X	x	X
pH	X	X	x	X
Inorganic nutrients	X	X	x	X
DOC/DON	X	X	x	X
POC/PON	X	X	x	x
Chl a/pheopigments	X	X	x	X
Flow cytometry[1]	X	X	x	X
EPS	X	X	x	X
EPS slides	X		x	
Cell taxonomy[2]	X	X	x	x
Bacterial activity	X	X	x	

DON/PON = dissolved/particulate organic nitrogen

Salinity, conductivity, total dissolved solids and temperature were determined with the hand held meter (HACH Sension 5). A desk-top meter was used to measure pH (Denver Instrument 250) after calibration with 3, 7 and 10 pH standards.

Subsamples for inorganic nutrients (NH_4, NO_2, NO_3, $Si(OH)_4$ and PO_4) were frozen in liquid nitrogen and then stored at -80°C for later analysis.

Duplicate DOC subsamples were filtered through precombusted Whatman GF/F filters. The filtrate was acidified with 50% H_2PO_4 and stored at 4ºC in the dark. POC subsamples were filtered onto precombusted Whatman GF/F filters and dried at 60°C for 24 h. We determined total chl *a* and pheopigment concentrations using the onboard fluorometer (10AU Turner Designs). Duplicate subsamples were filtered on Whatman GF/F filters (total chl *a*) after which the chl *a* was extracted for 18 to 24 h in 90% acetone.

Cell samples for taxonomy (20 to 250 ml) were preserved with either acidic lugols or buffered formaldehyde. Bacterial and protist samples were collected for both epifluorescent microscopy and flow cytometery analyses. Subsamples for flow cytometery (heterotrophic bacteria and pico/nanoplankton) were preserved with a final concentration of 0.1% glutaraldehyde and stored at -80°C. Subsamples for epifluorescence were preserved with formaldehyde (1% final concentration), stained with DAPI (4, 6-diamidino-2-phenylindole), at a final concentration of 1 µg ml^{-1}, and filtered onto 0.2 µm black Nuclepore filters. The prepared slides were stored at -80°C. The presence of active bacteria was investigated by incubating subsamples with 5-cyano-2,3-ditolyl tetrazolium chloride (CTC, final concentration 5 mM). The samples were incubated for 3 h at -1.5°C in the dark. Samples were preserved with a 5% final concentration of formalin and frozen.

EPS, defined as >0.4 µm acidic exopolysaccharides, were assessed with two methods. Bulk concentrations were estimated by Alcian blue staining of samples filtered on 47 mm 0.4 µm Nuclepore filters. EPS concentrations were measured colorimetrically (787 nm, onboard JENWAY 6300 spectrophotometer) after a 2 h extraction in 80% H_2SO_4. EPS slides were also prepared by filtering

subsamples on 25 mm 0.4 µm filters and staining with Alcian blue. The slides were prepared according to Logan et al. (1994), allowing for the observation of EPS using brightfield microscopy.

Acknowledgements
I greatly acknowledge all the hard work of the officers and crew during this leg. Thanks to CJ Mundy and Benoit Phillipe for all their help and expertise in the laboratory and in the field. Thanks also to Debbie Armstrong, Alexis Burt, Monika Pucko, for the sampling help on the latter half of the leg.

2.6.3. Marine Microbiology Group

Participants: Carles Pedros-Alìo- Institute de Cience de la Mar de Barcelona, Dan Nguyen, Maranger team- Université de Montréal

Introduction
Microorganisms are a heterogeneous group that include representatives of the three kingdoms of live, Archaea, Bacteria and Eukarya. These organisms drive biogeochemical processes in the ecosystem. Autotrophic microorganisms are the base of the Arctic trophic web, which comprises 7 orders of size magnitude, ranging from the smallest cell of less than 1 µm to the largest mammals. All of these organisms are strongly influenced by annual cycles of light, temperature and ice cover in terms of the composition and activity of the species present.

How microbes use organic and inorganic matter and how this influences other components of the food web? This knowledge is needed to better predict the consequences of natural or anthropogenic changes on these trophic dynamics. This will also help us to evaluate the system's ability to buffer these changes at short and long timescales.

Objectives
The measurements completed during this leg covered the work of 4 teams headed by Corina Brussard, Connie Lovejoy, Roxane Maranger and Carles Pedrós-Alió. We aimed to determine the diversity of

species present and the importance of the biogeochemical processes driven by these organisms during the spring season.

Leg 8 had two more specific objectives. First, intensify bacterial respiration in ice measurements to confirm results obtained during leg 8. Bacterial respiration in ice hasn't been asserted until now and could play an important role in carbon fluxes at the sea-ice-atmosphere interface, especially in the event of a warming arctic climate. We also hope to link bacterial respiration data with carbon lability using regrowth experiments.

Second, N2O measurements were also intensified on a time and spatial scale by switching to daily sampling. N2O is a gas produced by bacteria, with a more potent greenhouse effect than CO2. We will try to see how N2O is related with bacterial activity and how it's cycle could be affected by climate change

Sampling

The details of the stations sampled and measurements performed can be found in tables 1 and 2, respectively. The following parameters were sampled;

1. Molecular genetics

Samples for DNA were collected on every station at 4 different depths. Six l seawater samples were prefiltered through a 50 µm mesh and then seperated into 'large' and 'small' DNA fractions by filtration through a 3 µm and then a 0.2 µm polycarbonate filter. After collection samples were stored at -80 ºC until processing in the Lovejoy laboratory in Université Laval.

2. Gene expression (RNA)

Samples for RNA were collected as for DNA.

3. Chlorophyll concentration

Samples for chlorophyll analysis were taken on each station at six or seven different depths. For each sample, one liter of water was filtered through a Whatman GF/F filter for microorganisms larger than the nominal pore size of 0.7 µm. In addition, 3 µm prefiltered obtain the small fraction, which was finally filtered through a Whatman GF/F filter. Afer filtration, the filters were stored overnight at -20ºC. Subsequently, the filters were introduced in acetone 90% and placed in a refrigerator, in the dark. After 24 hours, the fluorescence of the extracts, before and after acidification with 3 drops of 5% HCl, was determined by means of a Turner TD-700 fluorometer.

4. HPLC

Samples for High Performance Liquid Chromatography (HPLC) analysis were taken on each station at six different depths. Two fractions were collected, one for the total fraction (down to 0.7 µm) and one for the small fraction (from 3 µm to 0.7 µm). Samples were stored at -80 ºC and will be analyzed at Laval University.

5. Virus

See report of Evans and Brussaard leg 8.

6. Organic matter

Using pre-combusted GF/F filters (47 mm diameter) in a passive filtration system (by gravity) samples for dissolved organic carbon (DOC), total organic carbon (TOC), amino acids and carbohydrates were taken. Samples without filtration for total phosphorus determination were also collected.

7. Bacteria and Archaea abundance

Microscope preparations for bacterial abundance estimations were prepared by filtering a small volume of water (20ml) fixed with formaldehyde and staining with DAPI. Microscopy slides were prepared on all stations at 6 different depths. Slides were frozen (-20°C) until counting on a epifluorescence microscope.

Bacterial preparations were also obtained in some stations using glutaraldehyde instead of formaldehyde as the fixative. These slides were frozen at -20 ºC until counting.

8. Ciliates

Samples for ciliates abundance and diversity were collected and preserved using a Lugol acid solution. These samples will be analyzed off the ship.

9. FISH: eukaryotes

The Fluorescent In Situ Hybridization is a powerful technique to study specific groups of microorganisms. Samples for FISH were collected on all stations at 6 different depths. Samples were stored at -80 ºC until analysis off the ship.

10. CARD – FISH: bacteria and archaea

Samples for the abundance and distribution of specific groups of prokaryotic microbes were collected in all stations at 6 different depths. These samples have been frozen at -20 ºC until its analysis with different oligonucleotide probes off the ship.

11. MarFISH: bacteria and archaea

Incubations with 3H-labeled leucine and C14-labeled bicarbonate were carried out to detect active prokaryotes in the uptake of these substrates at two depths (surface and base of the nitrocline). Leucine incubations lasted for 8 hours and bicarbonate incubations lasted for 24h always in the dark. After fixation, samples were filtered and filters stored at –80 to be analyzed on land. In combination with the FISH technique this can give information on the phylogenetic identity of these active microorganisms. Beside the MarFISH incubations, samples were incubated with C14-labeled bicarbonate (at a lower concentration) to measure bulk bicarbonate uptake by bacteria and archaea in the dark. These samples were incubated for 24 hours and subsequently filtered. The filters were exposed to HCl fumes overnight, and embedded in cocktail for the scintillation counter measurement.

12. Bacterivory – FLBs grazing

In order to acquire values of ingestion rates of bacteria by heterotrophic eukaryotes, Fluorescent Labelled Bacteria (FLB) obtained from a culture of *Brevundimonas diminuta* were used on bacterial grazing experiments. Triplicates and a 0.2 µm seawater filtered control with 10^5 cells/ml added were used. Samples for flagellates and bacterial microscopy observation and for bacterial production were collected at the beginning and after 48 hours of incubation at seawater temperature (cold-room). This experiment was conducted once during the leg.

13. Algivory – Micromonas grazing

Two grazing experiments with the *Micromonas* strain RCC497 were performed in order to calculate an ingestion rate of *Micromonas* cells by heterotrophic flagellates. For each experiment, two replicates of 2000 ml seawater filtered by 200 µm were incubated during 96 hours, at surface seawater temperature (-1.4 ºC). A control of 0.2 µm filtered seawater was run in the same conditions at the

same time. Samples for FISH (to observe *Micromonas* ingestion) and flow cytometry (to observe *Micromonas* disappearance) were taken.

14. Bacterial production

Bacterial production rates were measured at six depths for each station using the leucine incorporation method (^{3}H labelled leucine) with 4 hours incubation at in-situ temperature. Samples were taken at every station at six depths, and also from surface waters below the ice. Rates of incorporation of radio labelled leucine were calculated using the ship scintillation counter.

15. Respiration

Bacterial/community respiration rates were measured using the FIBOX, which measures O_2 depletion in time using sensors glued in 500ml Erlenmeyers. The consumption of O2 in time can be converted in CO2 production to compare carbon respiration rate to bacterial carbon production rates. Each experiment lasted for about 15 days and oxygen measurements were made every 1-2 days. The erlenmeyers were kept in the dark inside a cooler in a cold room. We intensified the number of experiment on ice during leg 8. We were able to measure respiration rates in melted sea ice and during the regrowth experiment.

16. ETS

Due to the low respiration rates in Arctic waters, a back-up method was also used to obtain respiration rate surrogates via ETS (Electron transport system activity). This is achieved by filtering a large quantity (8L-10L) of water on GF/F filters to collect live cells and freeze them (-80°C) as quick as possible. Once off the ship, filters will be defrozen and the living cells will be subject to enzymatic tests to measure activity.

17. N2O in the upper water column

Dissolved N2O measurements were carried out using the headspace equilibration method with 1.1 L of seawater. 3 samples were taken from 3 depths and will be analyzed off the ship for N2O on an electron capture detector (GC). We intensified measurements for N2O on leg 8b to gain resolution on time and spatial scales by switching to daily sampling.

18. Carbon lability and consumption

To measure these variables we carried out two regrowth experiments. One of them will be passed to the leg 8 team. These experiment work on the principle of re-inoculation of a natural bacterial community (ice-water interface) in filter sterilized (0,2um) water or melted ice samples. To make sure that bacteria would only be limited by C, we added NaNO3 and NaPO4 to insure a minimal growth medium. Each 48h, we took samples for DOC analyses in Montreal, and each 4 day samples for flow cytometry to determine bacterial abundance. We hope that the DOC measures will give us more information on the lability of the carbon contained in the ice. Bacterial production was measured at the beginning and end of the experiments. These incubation were joined to respiration measurements using the same samples to see if DOC could sustain bacterial processes over a period of time (15-20 days).

Other activities

The team participated in all social activities of the ship. Claire gave interviews to media members. We also helped other teams on the digging of holes in the ice and ice core sampling. We also provided 0.7 µm filtered seawater for the zooplancton team and help other temas whenever possible.

Note:
Carles Pedros-Aliò had to leave prematurely before the mid-leg change, for family reasons. The complete sampling plan couldn't be carried out for the first half of the leg. Were still able to complete most of the regular sampling activities without major compromises.

Acknowledgements
We would like to thank our Chief Scientists (Michel Gosselin, Jean-Éric Tremblay and Dave Barber), Captain Stéphane Julien and crew of the Amundsen for the excellent work done during leg 8. Thanks to Benoit Philippe, Christian Nozais, Chantal Lacoste, Maike Kramer, and Rodd Laing for there help collecting the ice cores and to Véronique Lago and Caroline Sévigny for there help with the rosette.

2.6.4. The significance of viruses for polar marine ecosystem functioning

PI: Corina Brussaard
Participant: Claire Evans (Dept. Biological Oceanography, Royal Netherlands Institute for Sea Research, PO Box 59, NL-1790 AB Den Burg, Texel, The Netherlands email: claire.evans@nioz.nl, phone: +31 (0)222 369449 (direct) or +31 (0)222 369300 (reception), fax: +31 (0)222 319674)

Background and Objectives

Microbial communities (phytoplankton, bacteria, Achaea, heterotrophic protozoa and viruses) comprise the majority of the biomass in the oceans and drive nutrient and energy cycling, and are thereby important components of polar food webs. With the emergent awareness that viruses are major players influencing biodiversity and biogeochemical processes the need to elucidate their role in polar ecosystems has been underlined as, despite their likely importance, their quantitative significance has barely been studied. We aimed to complete a comprehensive study of the viruses and viral mediated processes of the Arctic marine habitats encountered during legs 8 and 9 of the Circumpolar Flaw Lead Study. Samples will be taken and experiments performed on organisms from both the water column and the sea ice. The objectives of this study are; 1) To examine the abundance and composition of viruses and their prokaryotes and eukaryotic hosts (In collaboration with Prof. C Lovejoy University of Laval, 2) To determine viral induced mortality on both prokaryotic and eukaryotic microbial hosts alongside host growth rates and mortality due to grazing. 3) To gather a data set allowing comparison of the viruses and viral mediated processes of the Southern and Northern Polar regions. 4) To collect sample from which viruses might be isolated and therefore available for laboratory experiments.

Work onboard

A range of sampling was completed at four different station types which were; 'Level One' stations, 'Bacterial' water column stations, 'Algal' water column stations and 'Ice' stations. During the former RNA, DNA and pigments were sampled as part of a suite of other microbiologically-relevant measurements in collaboration with the other Microbiologist onboard (Prof. C Pedros-Alio leg 8A and Mr D Nguyen University of Montreal leg 8b). For more details see report of Mr D Nguyen. On bacterial water column stations measurements of abundance, diversity, grazing rate and viral-induced mortality were performed on the bacterial community at surface and/or chlorophyll maximum and bottom. On algal water column stations abundance, diversity, growth rate, viral lysis rate and grazing rate was determined on those algae present at the chlorophyll maximum. Finally at ice stations measurements were made to determine the abundance and diversity of the viruses and bacteria and the frequency of virus-infected bacteria. Details of the stations sampled are given in table one. At all experimental stations, samples were taken for viral diversity by concentrating 10 l volumes by 30 kDa ultrafiltration. These samples will be stored at -80 ºC until analysis by pulse field gel electrophoresis at the NIOZ. Samples for viral and bacterial abundance were fixed with glutaraldehyde, snap frozen and stored at -80 ºC for later analysis at NIOZ by flow cytomtery and SYBR Green.

Growth rates, viral lysis and grazing of the cyanobacteria, picoeukaryote, and nanoeukaryote communities present were determined by a dilution technique whereby whole water is combined with either 30 kDa filtered water (virus and grazer-free) or 0.4 um filtered water (grazer-free) in triplicate over a dilution series and incubated at *in situ* temperature and light conditions (environmental chamber). Fixed samples for algal enumeration were taken from all incubations at the start of the assay and after 24 h, allowing the calculation of growth rate. By plotting observed growth rate against the level of dilution the theoretical growth rate in the absence of mortality was calculated along with coefficients of grazing and viral induced mortality.

Rates of viral induced mortality of bacteria were determined by viral reduction assay. Briefly, the bacterial community was concentrated by tangential flow filtration and resuspended in viral free water generated by 30 kDa ultrafiltration. The production of viruses was followed by sampling for bacterial and viral abundance over a 12 h period (subsampling every 3 h). Rates of lysogenic infection of the

bacteria were determined in identical experiments with the addition of Mitomycin C, inducing lytic production of any lysogenic phage. In addition, rates of viral infection of bacteria will be elucidated by determining the frequency of infected cells which will be performed at the NIOZ on samples preserved with glutaraldehyde. Grazing of bacteria was assessed by an exclusion assay whereby bacterial numbers within incubations filtered to remove grazers 0.8 um were compared with whole water incubations containing grazers. Samples for virus isolation were collected from the chlorophyll maximum and will be screened against potential hosts at the NIOZ.

Table One. Stations sampled

Preliminary results

All measurements will be performed on preserved samples either at NIOZ for, flow cytometry of viruses, bacteria and phytoplankton, pulse field gel electrophoresis of the viral community, and transmission electron microscopy to determine levels of infected cells and at University of Laval for DNA, RNA and pigment samples.

2.7. Team 8

PI: Gary Stern (DFO, Freshwater Institute)
Participants: Feiyue Wang (University of Manitoba), Joanne DeLaronde (DFO, Freshwater Institute), Monika Pucko (PhD student, University of Manitoba), Amanda Chaulk (MSc student, University of Manitoba), Alexis Burt (MSc student, University of Manitoba), Jeffrey Latonas (MSc student, University of Manitoba), Garry Codling (Lancaster University, UK), Fiona Wong (Environment Canada)

Objectives
The overarching question this project hopes to answer is how climate variability in physical forcing and the biogeochemical response to this primary forcing will affect the cycling of contaminants in the Arctic Ocean. The contaminants that of primary interest are mercury (Hg), polychlorinated compounds such as hexachlorocyclohexane (HCH) and polychlorinated biphenols (PCBs), and perfluorinated alkylated substances (PFAS). Ultimately, we aim to relate changes in delivery and biogeochemical cycling of these contaminants to their levels in fish, marine mammals and the people who consume these tissues as part of their traditional diets.

Leg 8 is a continuation of the work started from November 2007. Below is a brief report summarizing the major scope of work during this leg.

2.7.1. Organic contaminants

Hexachlorocyclohexane (HCH) (Pucko)

Technical HCH is a mixture of several isomers, the most abundant being α-HCH (60-70%), γ-HCH (5-12%) and β-HCH (10-15%). Technical HCH and pure γ-HCH (lindane, pesticide active isomer) have been used for over 50 years and are now ubiquitous in water throughout the northern hemisphere with the highest levels found in the surface water layers near pack ice in the Arctic Ocean.

Technical HCH was banned or heavily restricted by China, the former Soviet Union and India between the mid-1980s and 1990. Concentrations of α-HCH in arctic air responded quickly to these large-scale usage changes and declined by an order of magnitude from the early 1980s to mid-1990s in steps that closely matched global usage and emission estimates. As a consequence, the direction of net gas exchange in arctic waters reversed from deposition in the 1980s to air-water equilibrium or volatilization in the mid-1990s.

The α-isomer is the prominent in Arctic air, water, biota and soil, and moves northward via cold-condensation, a process whereby the contaminant evades into the atmosphere, drifts with atmospheric currents, and condenses in colder climates where at colder temperatures increasingly favours the water and extensive ice cover inhibit further evasion. Hence the contaminant accumulates disproportionately in the Arctic.

HCH water sampling
Water (4L) was collected from the rosette every 4-6 days. Where feasible, transects across water bodies were collected. In the lab, water was pumped through a glass-fiber filter followed by an ENV+ solid-phase extraction (SPE) cartridge using peristaltic pumps. Filters and cartridges are frozen and brought back the Freshwater Institute for analysis. $^{18}\delta O$ were also collected at each site and depth where HCH samples were taken.

During leg 8 water profiles were sampled at stations: D43, 405b, 1011, 1806 and 9008.

HCH air sampling
The air sampler was set up on the bow of the ship on the starboard side along with each ice sampling. Samples are collected on a glass fiber filter and polyurethane foam (PUF) for analysis of organic contaminants. Air samples collection time ranged between 4 and 10 hours. Filters and PUFs were frozen at -20°C and shipped frozen back to the FWI for HCH contaminant analysis.
During leg 8 air was sampled at stations: D43, 1020A, F1, O1, O2, F2, 405b, 1011, 1806, 6010-M1, 9008.

HCH biotic sampling
The main purpose of this study is to link physical and biological processes to mercury/HCH levels in the food web and to target the pelagic food web biomagnification and bioaccumulation of HCH and mercury with stable isotopes and fatty acids. Thus, all biological samples collected will be measured for HCHs, total mercury and MeHg along with stable isotopes to place organisms into their associated trophic levels.

Zooplankton
Zooplankton samples were collected on a daily basis. Various zooplankton families were collected using the vertically towed Tucker net (mesh size 0.2 mm) from the moon pool. To obtain the species from under the ice (e.g. Calanus glacialis AF) vertical tows 0-60m were done from the ice with a Tucker net. Zooplankton was sorted into families, placed in plastic vials and Whirlpak bags and frozen until they can be analyzed for HCH, THg, MeHg, stable isotopes and fatty acids.

Zooplankton sampling stations for HCHs were the same as those for mercury analysis.

Algae
All the bottom ice cores were filtered through pre-weight GFF filters in order to get sea ice algae. The filters were frozen and taken to Winnipeg for further analysis.

HCH ice sampling
Ice samples for HCHs concentration and enantiomeric composition were collected. The samples for oxygen isotope composition ($\delta^{18}O$) and salinity were taken along with all ice samples. The ice samples were collected in collaboration with team 2 and the ice microstructure and physical analysis was made on all of them (see team 2 cruise report). Ice cores were cut according to ice microstructure into 15-40cm layers or the whole core was taken, melted (4-8L of water) and pumped through a glass-fiber filter followed by an ENV+ solid-phase extraction (SPE) cartridge using peristaltic pumps. Surface water (4L) and 5m water were sampled along with almost every ice sampling using a Niskin bottle. The cartridges and GFFs were stored in -80 °C and brought to the DFO (Winnipeg) for further chemical analysis.

Ice was sampled at stations: D43, 1020A, F1, F2 and 6010-M1.

HCH snow/brine sampling
At some sites snow/frost flowers were sampled for HCH analysis. Air was always sampled along with the snow/frost flowers sampling. Where possible, snow was sampled in layers. Snow/frost flowers sampling for HCH analysis was mostly done in collaboration with team 2 snow pit sampling (snow density, salinity, temperature and grain characteristics were measured). Snow/frost flowers samples were taken with a metal pan into plastic bags. After melting, 8L of melt water was pumped through a glass-fiber filter followed by an ENV+ solid-phase extraction (SPE) cartridge using peristaltic pumps. The cartridges and GFFs were stored in -80 °C and brought to the DFO (Winnipeg) for further chemical analysis.

Snow was sampled at stations: D43, F2.
Brine was sampled at stations: D43, F1 and F2.

Bacterial experiment
Bacterial cultures from 9 different depths in the water column cultured by Marcela Ewert (Jody Deming's team) during leg 5 were maintained throughout leg 8 and will be taken back to Winnipeg for HCH EF degradation experiments.

The role of the Arctic in the global cycling of Persistent Organic Pollutants – ARCPOP
(Codling, Halsall group)

Overview
The purpose of the Halsall group's work is to examine the transfer of persistent organic pollutants (POPs) between the key Arctic compartments of air, snow, sea-ice and seawater during the period following polar sunrise (leg 7) to early summer (leg 8). Organic contaminants of interest include the 'legacy' POPs, such as the organochorine pesticides and polychlorinated biphenyls, as well as 'emerging' contaminants such as the perfluorinated alkylated substances (PFAS) and select current-use pesticides. The transfer and fate of these chemicals in the Arctic marine environment is poorly understood and yet their 'cycling' between air-seawater is likely to be strongly controlled by seasonal fluctuations in sea-ice cover. In addition, the role of snow in transferring airborne contaminants to marine surfaces with subsequent uptake to the marine foodweb is also an area for investigation.

Sampling strategy
Integrated sampling was conducted whenever possible; combining air, snow and seawater sampling at various CFL stations during leg 8. Due to the diversity of target analytes, separate sampling equipment and strategies where adopted. These were roughly distributed between 'large volume' techniques for legacy POPs, and 'low volume' sampling methods/techniques for PFAS.

Air samples
Leg 8a a High-Volume (Hi-Vol) air sampler set up on a 50m power cable was deployed where possible off the ship on the starboard side beginning at site D-43 initial 48 h samples were taken for 'legacy' POPs, with the sampler deployed on the ice, approximately 50 m upwind of the ship. At another station the Hi-Vol was deployed for PFAS sampling using a PUF/XAD/PUF sandwich. A second onboard Hi-Vol air sampler on the bow was used for POPs sampling though may have ship contamination.

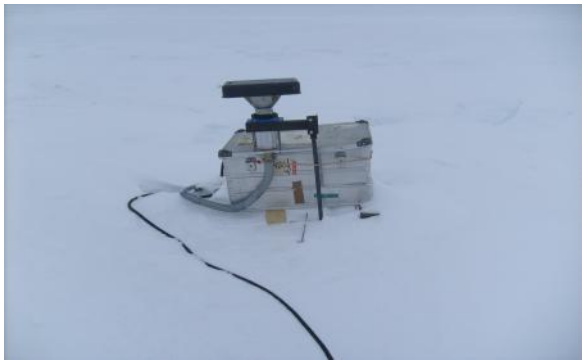

Figure 1. Hi-vol air sampler deployed on the ice at CFL station D43

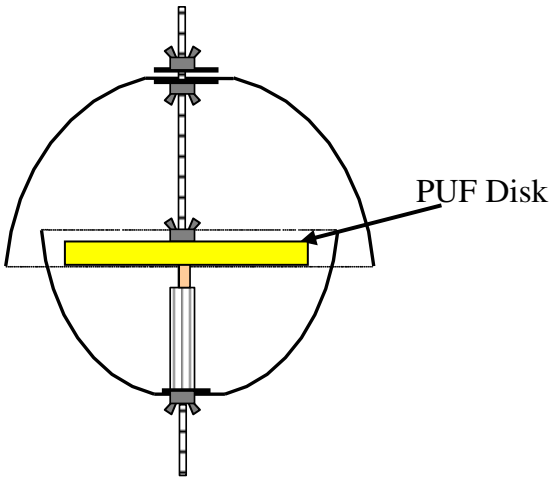
For Leg 8 (b) due to the proposed sampling schedual the ship would not remain static long enough for ice deployment so the HI-Vol was redeployed on to the top of the wheelhouse. This was not ideal as filter showed influence from ship but allowed for more consistent sampling regimes.

Passive air samplers (PUF-disk samplers) were deployed on Leg 7 and taken down at the end of Leg 8 (b) (2) were deployed at the stern of the ship, close to the aft labs, as well as within the benthic laboratory (1) to assess ship-based contamination, particularly for polychlorinated biphenyls (PCBs) and polybrominated diphenyl ethers (PBDEs - flame retardants). Elevated levels of these compounds

are typical of many marine research vessels and deployment of PUF-disk samplers will serve as a useful quality control for the contaminant group as a whole.

PUF-disk samplers were also deployed (3) on the meteorological mast at the bow of the ship at different heights and these may reflect true contaminant levels in the Arctic marine boundary layer, and will be compared to the aft samplers. Two PUF-disk samplers were placed on the top of bridge in proximity of the Hi-Vol position.



Schematic of PUF Disk passive sampler

Seawater samples

The onboard (teflon-lined) seawater line was used to collect large volume seawater samples for POPs. Seawater was sampled from the well-mixed surface layer (~7 m depth) and passed through an in-line filter and XAD-cartridge system, which operationally collects the respective particle-bound and dissolved fractions of POPs Problems were encountered with the seawater-line; notably rust-like deposits present in the water as well as erratic flow rates from the pump/tap. This resulted in clogged filters and low sample volumes. Nonetheless, seawater samples comprising of volumes of <500L were collected and will be analysed fro OC pesticides and PBDEs, although these samples may be compromised due to the rust deposits.

Figure 2. Onboard seawater sampling line in the Benthic lab

Low-volume samples (2-4L) were collected from beneath the sea-ice at interstitial and 5m depths. In open water surface and 5m low-volume samples were collected for PFAS.

For Leg 8 (b) due to the quality of the sample being produced from the on ship line an INFILTREX water system was used capable of pumping water through a filter for particulates and an XAD-2 filled

column for dissolved phase this was deployed 25m from the ship. Use was limited by the station sample lengths employed as a minimum of 24h on stable ice was required to get enough volume to sample.

Snow & ice samples
Three 50L gas-tight snow sampling cans were deployed at 10 stations over the course of the 6 weeks. The type of snow collected was largely dependent on the location and environmental conditions.

Figure 3. Snow-can meltwater extraction

Figure 4. Snow-cans deployed on the ice

Contaminant concentrations in snow will be related to snow physical properties as well as concentrations observed in air and underlying seawater. Snow-cans were also used to collect and melt sea-ice cores to examine contaminant levels in ice. Low volume (2-4 L) snowmelt and ice-core samples were also taken for PFAS. In open water free ice was collected on a 'grab' basis if available looking only for new ice.

Brine
Low volume (2-4L) of brine was also collected at 4 sites for analysis for PFAS compounds. These were collected as a sideline to the original project plan to determine if PFAS potentially detected in Ice and snow exist in greater or lesser concentrations in brine.

Currently Used Pesticides (CUPs) and Perfluoro Compounds in the Atmosphere (Wong)

The fate of pesticides applied to agricultural fields is of great interest because they are manufactured to be toxic to biota and some organisms. Currently used pesticides (CUPs) are generally more volatile and less persistent than the older style organochlorine pesticides, such as HCHs, but they can still undergo atmospheric transport through volatilization and deposition followed by reemissions. They ultimately make their way to sensitive ecosystems including the Canadian Arctic. CUPs include: dacthal, chlorothalonil, endosulfan and Chlorpyrifos, which have been reported in Arctic air (Hung et al., 2005; Jantunen et al., 2007, Shen et al., 2005; Pozo et al., 2006; Chernyak et al., 1996), seawater (Jantunen et al., 2007; Chernyak et al., 1996; Weber et al., 2006), sub-arctic/arctic lake water (Muir et al., 2004), snow (Hermanson et al., 2005; Chernyak et al., 1996) and fog (Chernyak et al., 1996). Perfluoro chemicals are emerging persistent organic pollutants which are found in a wide range of applications such as paints, packaging, lubricants, firefighting foams, stain repellents and cookware. They are found in Arctic where they accumulated in the food chain and in the atmosphere (Butt et al., XXX, Shoeib et al., 2006). There are is little known about their atmospheric levels in the Arctic.

During Leg 8B, air (~1200m^3, n=10) were continuously collected to determine occurrence and levels of CUPs. Air was drawn at a flow rate of 0.5 m^3/min, through a glass fiber filter (Whatman,

Maidstone, England, 20.3 x 25.4 cm, EPM 2000, collects 99% of particles >0.3µm) followed by two plugs of polyurethane foam (PUF), each 8 cm diameter x 7.5 cm tall, that collect the gaseous phase. Water samples (n=5) were also collected by pushing 100L of water through a glass fibre filter (GFF, 142mm) or a high capacity filter followed by a column of XAD-2 resin (Amberlite, macroreticular styrene divinylbenzene copolymer, 20-60 mesh size, Rohm and Haas, Supelco, Bellefonte PA, USA, 1.5 cm i.d., 75 mL settled volume) to concentrate the dissolved fraction. Sampling will continue during Leg 9B.

A separate set of air samples were collected for perfluoro compounds. Three ~350 m^3 air samples were taken with a PS-1 (Tisch Environmental, Village of Cleves, OH, U.S.A.) sampler, consisting of 7.6 cm diameter GFF followed by PUF-XAD-2-PUF plug sandwaich (6.8 cm diameter). These were collected for Mahiba Shoeib at Environment Canada, Toronto. Sampling will be continued in Leg 9B and 10A.

α-HCH Flux Experiments

Hexachlorocyclohexanes (HCHs) are the most abundant organochlorine pesticides in Arctic air due to their facile atmospheric deposition in the cold environment and slow degradation rates. In the past two decades, there has been a reduction in primary emissions of technical HCH with an accompanying decline in atmospheric HCHs concentrations. As a result, a reversed direction of air-water flux from net deposition to net volatilization has been observed in some arctic regions. This study was carried out to determine the gas exchange of HCHs using gradients of HCH concentrations and enantiomer fractions (EF) of α-HCH, where EF = concentrations of (+)/[(+) + (–)] enantiomers.

Air samples were collected at three heights above the surface, at ~1m, ~6m and ~12m to determine the flux of α- HCH and its enantiomers (35 m^3, n=27). A modified PS-1 (Tisch Environmental, Village of Cleves, OH, U.S.A.) sampler was used consisting of 7.6 cm diameter GFF followed by one PUF plug (6.8 cm diameter x 4.2 cm). Parallel low volume water samples (4L, n=6) were also collected but passing water through a glass fibre filter (47mm) followed by a ENV+ (200mg, Jones Chromatography) SPE cartridge.

Based on the results from Leg 1 (July 27 – August 16), which traveled from Quebec City to the Labrador Sea, through Hudson Strait and along a southern route in Hudson Bay to Churchill, Manitoba. It is found that α-HCH levels in air collected near the water surface at Hudson Bay were ~10% higher than those collected at 15 m above water. Similarly, EFs of α-HCH in air sampled closest to the water are expected to approach the nonracemic EFs in the surface water and tend toward more nearly racemic values with height. Sampling will continue during Leg 9B.

Polychlorinated biphenyls (PCBs) project (leg 8A) (DeLaronde)

Participants: Joanne DeLaronde (DFO, Freshwater Institute, Winnipeg, MB.), Monika Pucko (PhD candidate, DFO and University of Manitoba)
Project members: Robie MacDonald (DFO, Institute of Ocean Sciences, Sidney BC), Gary Stern (DFO, Freshwater Institute, Winnipeg MB.), Zou Zou Kuzyk (PhD candidate, University of Manitoba)

General objective

As a result of extensive studies over the past 30 years, much has been learned about traditional contaminants like PCBs and their pathways, processes and effects in the Canadian Arctic. One of the only areas remaining as a major knowledge gap is Arctic seawater. PCB concentration data for Arctic seawaters are rare, largely because opportunities to collect the samples are rare, and also because it is challenging to sample and analyze PCBs at the low concentrations that occur in Arctic seawater without contamination or other biases. As we learn more about these challenges, increasingly it looks like some of the data collected in the past – including some in the Canadian Arctic – may be wrong.

The goal of this project is to obtain new, trustworthy measurements of dissolved PCB concentrations in Canadian Arctic Ocean seawater, guided by recent developments in our understanding of the challenges associated with this work, and how they can be overcome.

Equipment preparation and sampling techniques

Our group's experience with sampling Arctic seawater for contaminants in the course of the Canadian Arctic Shelf Exchange Study (CASES) and ArcticNet cruises has made us very cognizant of the challenges of this kind of sampling generally and also more specifically, for the conditions aboard Canadian Arctic research vessels.

Ultra-clean procedures were considered from the time that sampling materials (XAD-2 resin and glass fiber filters) were first prepared, through their storage and handling in the field and during and after sample collection. In preparation for sampling, XAD-2 resins were rigorously cleaned, proofed and packaged at AXYS Analytical Services Ltd. The filters were pre-combusted, stored in baked aluminum envelopes and vacuum sealed in plastic. New Teflon tubing and connectors as well as the pump filter plates were cleaned with hexane and vacuum sealed in plastic. These components were prepared at the Freshwater Institute, DFO, Winnipeg. The cleaned materials were stored on the ship in a vacuum seals bags inside a clean cooler to minimize their contact with the ship's atmosphere and other potential contamination sources.

Ideally, initial filter and column changes were to be conducted away from the ship on the sea ice. Because there was considerable retrofitting required due to the incompatibility of the stainless steel columns with the configuration of the pumps and the lack of the proper hardware this was not possible. The columns and filters were initially installed on the pumps in a cabin inside the ship. This was done as cleanly as possible, wearing latex gloves and ensuring critical pieces were kept clean and

off any potentially contaminated surfaces. Any open ends (water intake and outlet lines) were sealed with parafilm until deployment.

Two in situ pump systems (Infiltrex and SeaStar) were deployed beneath the sea ice to a depth of 15 m thus sampling Arctic Ocean seawater from the sea ice (rather than a ship) as a platform. The sampling area was upwind and approximately 500 m away of the ship to reduce the effects of the ships atmosphere.

The systems are equipped with glass fibre filters to collect suspended particulates (and associated PCBs) and stainless steel columns containing XAD-2 resin, which extract dissolved PCBs. During leg 8A the project was limited by the number of pre-cleaned columns available. Of the five columns, two were treated as procedural blanks and two as samples. Sampling with one column was not completed due to pump problems.

Two blanks were obtained by passing 1-L of seawater through each pumping system. The expected blank levels for filters and XAD-2 resin columns are in the order of 3-8 pg absolute.

Samples consist of between 250-400 L of seawater**.** (400-600 L would have been preferred.) Assuming that PCB concentrations in Canadian Arctic seawater are similar to recently reported values for the European Arctic (e.g., $\Sigma PCBs_{15}$=0.54-1.96 pg/L, PCB congener 52 concentrations = 0.10-0.24 pg/L; (Gustafsson et al., 2005)), sample volumes of 400-600 L should produce readily quantifiable PCB congener concentrations (40-120 pg absolute).

After the required volume of water was sampled, the columns and GF/F were placed in ziploc bags, sealed and returned to the ship where they were vacuum sealed. The columns were stored at 2ºC and the GF/F at -24ºC. When possible the columns and filters were exchanged in the in situ pump system on the ice at the sampling site. This was not always possible due to the cold conditions. On occasion the intake line and the column would freeze when he pump was removed from the water, causing it to shut down due to low flow. It was necessary to bring the pump back on board to thaw. If this was the case, all open ends were sealed with parafilm before bringing the unit on board the ship. The Infiltrex also requires the use of computer software to program flow rates and volumes prior to every deployment. Again, there were problems when it was extremely cold and the system had to be returned to the ship to warm up. Ideally we require a heated tent or some other form of shelter to not deviate from our intended protocol. The uncertainty of the ship movements (due to weather) was somewhat prohibitive to this project.

Preparing pumps for deployment:

Infiltrex

SeaStar

Samples collected

Date	Pump System	Sample Type	Column I.D.	Location		Depth (m)		total pumping time	total volume (L)
				Lat.	Long.	sample	bottom		
29-Apr-08	Infiltrex	blank	4415-26	70º 44.65 N	123º 33.105 W	15	545	10 minutes	1.0
29-Apr-08	Infiltrex	sample	4415-27	70º 44.65 N	123º 33.105 W	15	545	43.4 hours	392.0
30-Apr-08	SeaStar	blank	4415-28	70º 46.466 N	123º 54.127 W	15	462	10 minutes	1.1
09-May-08	SeaStar	sample	4415-29	70º 04.451 N	125º 09.051 W	15	31.5	27 hours	248.62

All samples and blanks pumped at a rate of 150 ml/min.

PCB congeners will be analyzed at AXYS Analytical Services Ltd. by high-resolution gas chromatography/mass spectrometry (US EPA method 1668A). Samples are analyzed in batches of 12-15 or less and a blank, spike and/or duplicate is analyzed with each batch.

This work will be continued during CFL Leg 9A.

Thanks to Stéphane Julien, Julio Salcedo and Garry Codling for their help!

2.7.2. Mercury

PI: Feiyue Wang (University of Manitoba)

Introduction

Mercury levels in marine mammals and fish are an ongoing concern in Arctic regions because of their inclusion in traditional subsistence diets among indigenous peoples in northern regions. Successful strategies to mitigate health impacts related to Hg in human diets require an understanding of both the social and cultural perspective of northern communities, as well as the natural environmental processes that lead to Hg in food resources. Our research on Hg in the Arctic is focused on determining the environmental processes responsible for the distribution and speciation of Hg in

Arctic marine ecosystems, for the purpose of supporting the development of strategies to lessen the impact of Hg on human and ecosystem health. Our specific objective during the CFL is to determine the **net** atmospheric flux of Hg to the aquatic ecosystem.

Atmospheric Mercury Speciation

Two systems have been running constantly during Leg 8 for real-time atmospheric mercury speciation monitoring in the air. In Leg 8, these two systems were operated by Dr. Fei Wang and Jeff Latonas.

Mercury Speciation System (SN323)
This system includes a Tekran 1135, a Tekran 1130, a Tekran 1130 Pump, and a Tekran 2537B (SN323). It provides real-time atmospheric Hg measurements for gaseous elemental mercury (GEM; every 5 min), particulate mercury (Hg_P) and reactive gaseous mercury (RGM; once every 3 hours). In leg 7 we had an additional 2537A monitoring GEM alongside SN323, however we lost use of that instrument due to a hardware problem. The system was installed in Leg 5 and has been continuously working without major problems. During Leg 8, we lost one day of data on April 25 due to unexpected computer shutdown and associated data logging problem.

Small scale mercury depletion event (MDE) episodes occurred throughout May 10, the GEM never dropped to zero as it did during Leg 7. Starting around May 6, the RGM concentration exceeded that of Hg_P, a phenomenon commonly observed during the later stage of MDEs.

GEM started to increase around May 10; levels up to 5 ng/m^3 were recorded, suggesting the end of the MDE season, degassing of dissolved gaseous mercury (DGM) is likely increasing as the ocean becomes more open. After the spike of GEM which began on May 10th, values returned to normal ~1.5ng/m^3. On May 27-29th the ship moved back north to the top of banks island, while up there two isolated depletion events were noted, we also seem to have a clear predominance of RGM since May 6th even though the frequency and depth of these depletions is low.

The glassware in the 1130/1135 speciation unit was changed on May 19th as well as June 02 including the RGM denuder and particulate mercury filter and pyrolyzer.

Total Atmospheric Mercury System (SN051)
We are also monitoring Total mercury (Hg_t) through a Tekran 1105 arctic pyrozlyzer unit which heats the sample to 900^{o}C before analysis by another Tekran 2537A (SN051), During Leg 7 Sandy Steffen modified this system to allow for the measurement of both ambient – total gaseous mercury (TGM) and heated/pyrolysed- total atmospheric mercury (TAM) in air by installing a switching valve which did 3 samples from the ambient line followed by 3 samples from the heated line. This later caused an electrical issue with the 2537 and the switching valve had to be removed; as of May 17th SN051 has been running on the heated air only.

During Leg 8, we replaced the Au Traps on the SN051 unit, and the unit has been stable and running well. A series of standard injections were performed on May 31st and the results were good.

Gaseous Elemental Mercury (SN071)
On May 20th it was decided that we would no longer be able to deploy our mercury speciation sled (Tekran 1130/1135/2537) onto the ice for any significant period of time, so the Tekran 2537 which was installed in that sled was removed and installed into the foredeck lab. In leg 7 we lost the use of the Tekran 2537 which was monitoring GEM alongside the SN323 speciation system due to a hardware malfunction. SN071 was installed on May 20th and began measurements of GEM in ambient air on May 24th.

The initial readings for ambient air were high and not corresponding to values measured by the other instruments. On may 31 a set of standard injections was performed to calculate a new permeation rate

for the internal mercury calibration source. This new value was inserted into SN071 and values were confirmed with additional injections.

Mercury in Surface Snow and Snow Pits

This work was done mainly by Amanda Chaulk during Leg 8. Time series of surface snow samples were collected whenever possible during Leg 8. The samples were analyzed within 1-3 days at PILMS. We continuously see the high Hg concentrations in surface snow. During the beginning of May, mercury concentrations in surface snow began to decline to levels observed earlier in the season pre-mercury depletion event. However, recent samples from the end of the leg have shown mercury concentrations in snow at higher levels observed earlier in the leg.

Snowpit samples were also taken at D43 (10cm) and F2 (70cm). The F2 snow pit showed low mercury concentrations (<10ppt) both at the surface and throughout the pit. The D43 showed some variation, having a higher mercury concentration at the top and declining concentration with depth.

Mercury in Ice, Brine Drainage and Melt Ponds

This work was done mainly by Amanda Chaulk during Leg 8. Ice cores were taken at stations D43, F2, D45, M1, and F5. The ice-core taken at M1 is a multi-year ice core 3.8meters long; this is the first time multi-year ice has been sampled during CFL. All ice cores were cut into partitions based on microstructure and individually scraped with clean gloves and an acid cleaned and tested ceramic blade. A new pair of gloves was used for each piece of core. The core was cut in half so each piece would be duplicate. During scraping blanks were also done; a zip-lock bag was filled with milli-Q water and allowed to freeze in the freezer lab while other cores were being scraped. The knife was wiped with a clean lab wiper and inserted into the blank bag, scraped along the ice or sloshed around in the water.

Brine time series were only collected at two sites during leg 8, D43 and F2. A single brine depth series was sampled at F5 as well. Brine wells were dug at 20cm, 40cm, 60cm, 80cm, and 100cm. The holes were covered and brine allowed to seep in. The brine was sampled twice per day with an acid cleaned and tested turkey baster, field blanks were also done by sucking milli-Q water into the baster and releasing it into a falcon tube. With the onset of the summer melt, the brine salinities as well as mercury concentrations decreased. Despite lower concentrations, brine data still showed similar trends to those observed in leg 7 (decreased mercury concentration the deeper the brine hole).

Leg 8 marked the first time melt ponds were observed. These were sampled at station F6, using an acid cleaned and tested turkey baster. Melt ponds were observed both with and without a thin ice cover over top, samples from both were taken and a difference in mercury concentrations was observed between those that were covered and those that were not. Field blanks were also done when sampling melt ponds. The thin ice cover over top of a melt pond was sampled as well.

Alexis Burt (dirty) and Amanda Chaulk (clean) sampling a melt pond on June 2, 2008

Mercury in Seawater

Water profiles were collected by the contaminants team, and analysed by Amanda Chaulk in PILMS. We collected seawater Hg depth samples from a total of 5 sites in Amundsen Gulf and Franklin Bay. Samples from the 10 m depth to the seafloor were collected with the ship-based Rosette sampling equipment in PVC "Niskin-style" sample bottles remotely operated from onboard the ship. Supplementary surface water samples from 0 to 10 m in depth were collected by a PVC Niskin water sampling bottle (General Oceanics, Miami, Florida) from a hole or open lead within a few hundred meters of the ship and within three hours of the Rosette collection. Within each profile, 11 to 20 different depths were sampled (including Niskin sampling), producing high resolution profiles for total Hg (Hg_T). At each depth sampled for Hg_T, water was also collected for $\delta^{18}O$ analysis in tightly sealed glass scintillation vials. After collection of $\delta^{18}O$ samples, bottles were further sealed with parafilm and stored at 4°C.

Samples for Hg_T analysis were preserved by 0.5% HCl and 0.5% BrCl, stored at 4°C, and analyzed within 1-3 days by cold vapour atomic fluorescence spectrophotometry (CVAFS) the Portable In Situ Laboratory for Mercury Speciation (PILMS) onboard the CCGS Amundsen.

Hg_T levels measured during Leg 8 were very low, averaging roughly 1 pM (0.2 ng/L) throughout the water column. These values are comparable with those measured during Leg 7. One exception was the profile taken from D43, where very high Hg concentrations (up to 8 ng/L) were found at a few depths. Since the precision of the 3 replicates was very good and since concentrations levels at other depths remained very low (< 0.5 ng/L), these high levels cannot be explained by contamination during sampling or sample preservation. Therefore, they were either due to contamination of the corresponding rosette bottles, or were true measurements of some exceptionally high Hg levels. We will further verify this with other ancillary data (e.g., nutrients, $\delta^{18}O$).

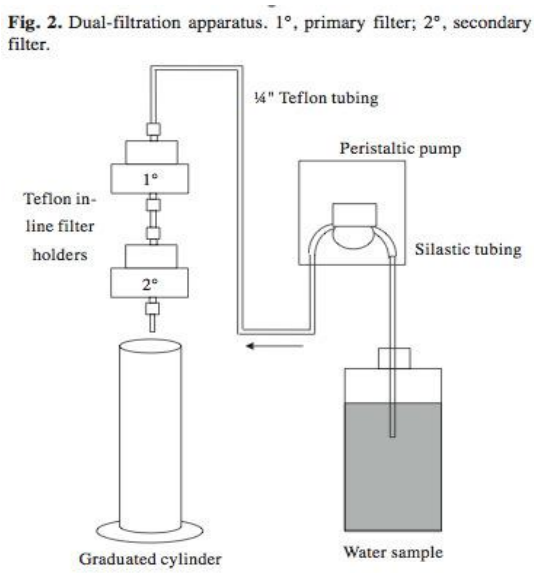
During Leg 8, the Niskin bottle used to collect surface water broke several times preventing the collection of full water profiles. Despite being fixed with contact cement several times by Jeffrey Latonas, the Niskin would break again fairly quickly.

Mercury in Phytoplankton and Zooplankton

Algae (Hg, MeHg)
Phytoplankton samples were taken in conjunction with zooplankton tows. Samples were sieved through 710µm, 350µm, 150µm, 50µm and 20µm mesh and frozen. Samples were also preserved with lugol's for speciation.

Phytoplankton was collected at stations D43, F2, 405, and F6. At open water stations, phytoplankton was collected with a 20um mesh net (stations 1011, 1806, 9008 and 405). The rosette was used to collect phytoplankton at the chlo max (stations 405B, 1806, 9008, and 405) these samples were filtered as below.

Under-ice algae was collected from the ice-water interface with a battery powered pump on a metre long under ice arm. These samples were filtered onto pre-combusted and weighed glass fibre filters (GF/F) for chlorophyll a, dry mass, and filtered in series with a clean set up for mercury, with a blank (see figure). The filters were frozen, and will be shipped to Winnipeg for further analysis. Bulk samples were frozen. Ice interface algae was collected at stations D43, F1, F2, 1011, D44, and F6.



Filtration set up for algal Hg (exception: the peristaltic pump is between the filters and the waste container)

Ice algae was collected by coring.
Ice algae was collected at stations D43, F1, F2, 1011 (melted in the freezer), and D45.

Zooplankton
Zooplankton samples were collected during the leg. Various zooplankton families were collected using the vertically towed Tucker net (200µm mesh) from the moon pool in ice covered areas, and when in open water, horizontal/oblique tows were done on the foredeck with a double Tucker net (500µm mesh) and vertical tows were done with the monster net (3x200µm, 1x500µm mesh nets). Zooplankton was sorted into families, or to genus and species where possible, placed in plastic vials and Whirlpak bags and frozen until they can be analyzed for THg, MeHg, stable isotopes and fatty acids. Common species found were *Calanus hyperboreus*, *Calanus glacialis, Paraeuchaeta glacialis*, *Sagitta elegans, Sagitta maxima*, *Themisto abyssorum*, *Themisto libellula, Metridia longa, Ostracoda* sp., Cnidarians, and Ctenophores. Some less common species found were *Cleone limacina*, *Gaidius* sp., *Hyperoche* sp., Euphasiids, and *Pandalus* sp. Zooplankton was collected at station D43 (x3) on leg 8a, and at stations F2, 405b, 1011, 1806, 8010, 9008, D44, D45, 405, and F6 for a total of 17 zooplankton hauls leg 8b.

Methylmercury (MeHg)

This work was done by Dr. Fei Wang. Progress was made during Leg 7 by Alex Hare and Debbie Armstrong in setting up the system. They were able to get a good calibration curve from MeHg standards. During Leg 8 we were able to reproduce the curve with similar intensity. However, we did not do any analysis until May 13 due to the ship movement. We carried out the distillation, but the detector was not stable for the ethylation and analysis to continue. The noise level was ~800 instead of 38 before the ship moved out from D43. The high noise was either due to the aged lamp (which was unlikely as it was replaced in Leg 7), or damage due to the ship movement.

Since a new automated system was ordered and is expected to arrive at the beginning of Leg 9, it was decided that the MeHg work be delayed until Leg 9.

Samples collected from Leg 7 were kept in the fridge and should be OK if analyzed in June according to the U.S. EPA protocol.

Leg 9

6 June – 17 July 2008

edited and compiled by David Barber and C.J. Mundy (Chief Scientists)

1. General overview

1.1. Introduction

On behalf of the scientific crew, I would like to express our sincere gratitude to Captain Lise Marchand, the officers and the crew of the Canadian Coast Guard Ship Amundsen for their comprehension, professionalism and camaraderie that helped make leg 9 of CFL a great success.

One of the main objectives of the CFL study was to compare and contrast the flaw lead system with that of the surrounding fast ice. With respect to this objective, leg 9 (5 June ï 17 July, 2008) encompassed an important transitional period where the fast ice rapidly ablated and broke-up giving way to an increasing polynya extent. This transition provided unique logistical challenges throughout the leg. Perhaps the most prominent of these challenges was the change from ice operations during leg 9A to open water operations during leg 9B. Leg 9 also provided for some unique opportunities and discoveries. For example, some of the highlights of the leg included: a unique sampling transect from marine waters through a river plume and into the fast ice edge; monitoring the melt progression of 2 shallow coastal bays (Franklin and Darnley Bay) from a thick winter ice cover through to complete break-up concluding with open water stations in both bays; observations of very high and sustained biological activity underneath the melting ice cover (i.e., prior to ice break-up in the bays); and the first detailed oceanographic transect of MðClure Strait, north of Banks Island. During leg 9, we also had a very successful community visit in Ulukhaktok (Holman).

1.2. Personnel

Leg 9 scientific and media participants included 55 scientific personnel, 7 media personnel and 1 wildlife observer (Table 1). The high number of scientific personnel was mainly due to the switch in operations from ice to open water that required different expertise and therefore, personnel. During leg 9A, 1 ï 2 media personnel were exchanged weekly allowing for 5 journalists from the World Federation of Science Journalists (WFSJ) to visit the ship. Two journalists from the WFSJ reported from the ship during leg 9B.

Table 1. Scientific and media personnel of CFL leg 9.

1.3. Scientific operations

A log of all scientific ship operations recorded by the Amundsenôs officer-on-watch is provided below. During leg 9A, operations were largely in the ice cover of Franklin Bay (Stations FB5 and 7) and Darnely Bay (Station F7; Figure 1a). While in the ice cover, all on-ship operations were accomplished through the moonpool. In order to collect samples from the ice and surface waters, scientific operations also involved off-ship sampling. Another integral part of leg 9A was the dive program where SCUBA divers collected samples and made measurements underneath the sea ice for numerous scientific personnel on the ship.

Scientific log recorded by the CCGS Amundsen officer-on-watch.

The general schedule of leg 9A was 2 to 3 days in each bay, followed by an open water station. The open water stations sampled during leg 9A include mooring station 405b and hotspot station 1216 east of Cape Bathurst. On the week of June 14, the science steering committee opted to sample along a transect perpendicular to the ice edge instead of a dedicated full open water station. The transect is plotted in Figure 1b. The decision to sample this transect was made in response to an observation of a spring freshet plume from the Horton River extending along the ice edge (observed on MODIS satellite imagery) and the appearance of numerous whales along the ice edge (observed during aerial mammal surveys) during the same time period. The transect was positioned to start in open water unaffected by the river plume (station FB00) cross the river plume (stations FB1 ï FB3) and end into the ice edge (stations FB4 ï FB7; Figure 1b).

During leg 9B, we were also able to begin operations with the moving vehicle profiler (MVP), a towable instrument that monitors conductivity, temperature, depth, fluorescence and dissolved oxygen. The MVP was used for surface water profiles near the ice edge during the ice edge transect on 14-15 June and during 2 short (20 ï 30 km) transects. The first of these transects was across the shelf break from the tip of Cape Bathurst and east, whereas the second transect was from the south to north exiting from Darnley Bay.

During leg 9B, operations were shifted from in the ice to open water. In order to maximize productivity, this meant switching from moonpool to on-deck operations. Furthermore, science and logistics were changed from days to 24-hour operations. As a result we were able to sample important transect lines throughout the entire polynya. During leg 9B we sampled 9 full stations (adding to the 4 full stations sampled during leg 9A), 4 basic stations, 4 MVP transects and numerous nutrient and CTD stations completing CFL transect lines 1200, 421-435, 6000 (west of Banks Island), 2000 (MðClure Strait), 410-420, 1900 and 1100. We also sampled water from the Mackenzie and Horton rivers via helicopter as well as a full station at D33/34 (a drifting ice station sampled for more than 2 weeks during leg 7).

Scientific operations ended the evening of 13 July, 2008. On 14 July we visited the community of Ulukhaktok (Holman). The schedule of the community visit is provided below. During the visit we presented on the science and logistics of CFL to 4 school groups of 15 ï 20 students each during the day. At night we invited 16 members from the Ulukhaktok HTC, Elders Committee and Community Corporation to join us for a science tour, supper and a formal presentation followed by a culture exchange and informal discussions.

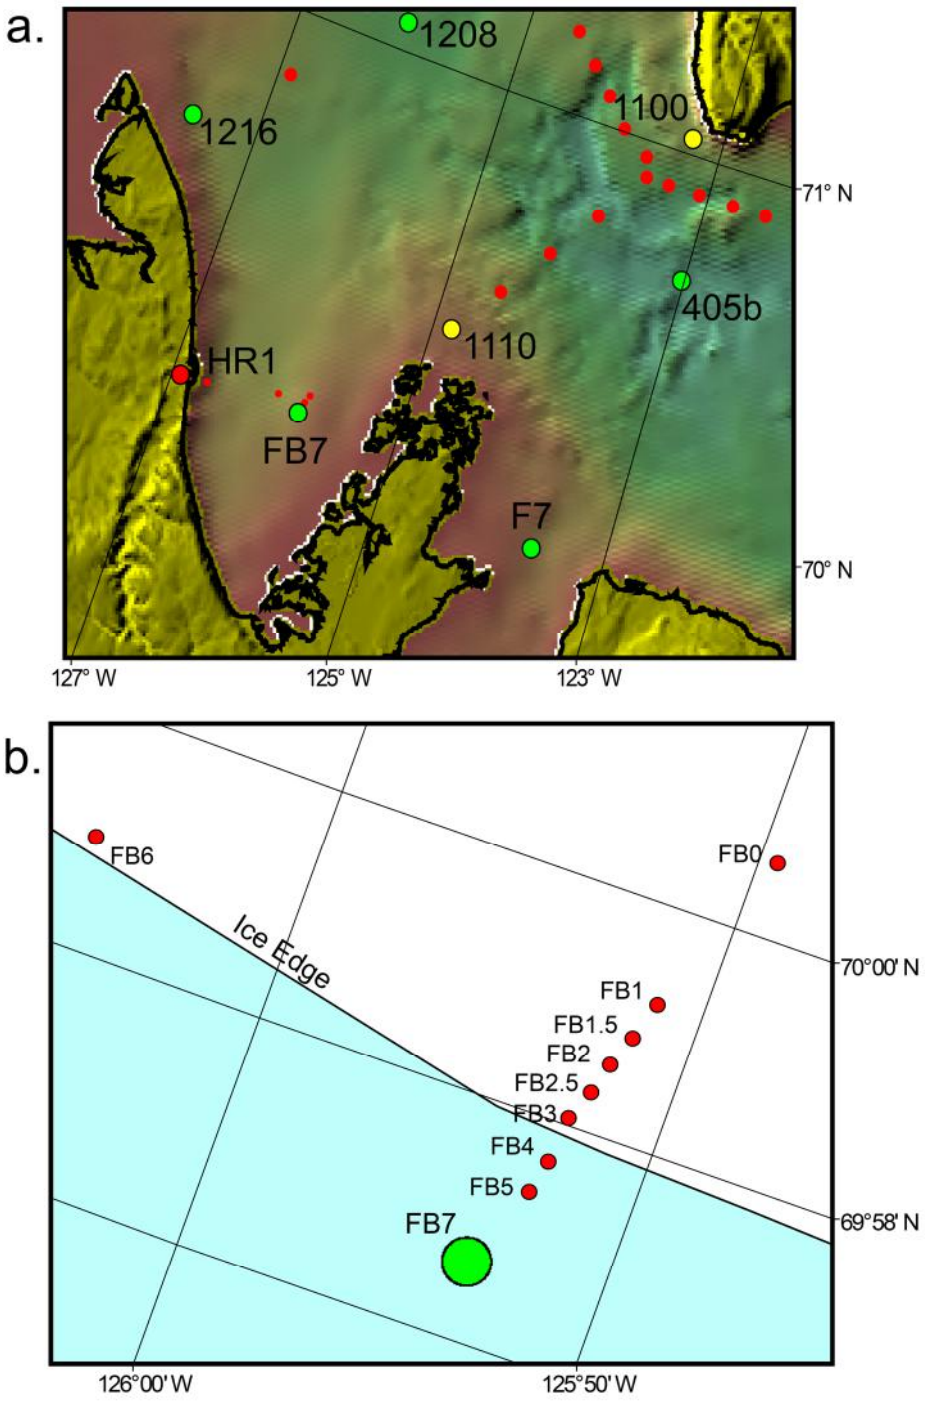

Figure 1. (a) Map of Franklin Bay and Darnley Bay highlighting the location of stations sampled during leg 9A (Sta. FB0 ï FB7, 405b, F7, HR1 and 1216) ï red dots are CTD and Nutrient stations, yellow dots are basic stations and green dots are full stations. (b) Close up of ice edge transect accomplished in Franklin Bay on 14-16 June, 2008 ï red dots are Basic stations, green dot is the full station, FB7.

Schedule of Ulukhaktok Community Visit, 14 July, 2008

1st school group
picked up from Ulukhaktok at 9:15 am
dropped off at 12:40 pm

2nd school group
picked up from Ulukhaktok at 10:20 am
dropped off at 1:40 pm

3rd school group
picked up from Ulukhaktok at 12:40 pm
dropped off at 2:50 pm

4th school group
picked up from Ulukhaktok at 1:40 pm
dropped off at 3:50 pm

3:50 pm ï 16 members of the HTC, Community Corporation and Elders
embark from Ulukhaktok
4:20 pm ï 5:30 pm ï Ship tour
5:30 pm ï 6:30 pm ï Supper
6:45 pm ï 7:00 pm ï CFL presentation
7:00 pm ï 8:00 pm ï ñice breakerò gathering
8:00 pm ï 9:00 pm ï Community members disembark

From 15 -17 July, we transited to Kugluktuk and accomplished the crew exchange for the start of leg 10.

2. Team reports

2.1. Team 1

PI: Yves Gratton (INRS-ETE, 490, Rue de la Couronne, Québec)
Participants: Véronique Lago, Sarah Dyck, Charles Brouard and Yves Gratton (INRS-ETE, 490, Rue de la Couronne, Québec)

2.1.1. CTD/Rosette

Objective
Description of water masses and general circulation over a year in the Beaufort Sea and Amundsen Gulf.

CTD-rosette

Materials
Physical parameters were recorded using a ship mounted RDI Ocean Surveyor ADCP (150kHz), and a rosette frame equipped with 24 bottles of 12 L and the following sensors:

Table 1: Sensors used on the Rosette

Photo	Item	Manufacturer	Type & Properties	Serial Number
	CTD	SeaBird	SBE-911 Sampling rate : 24 Hz

Notes: [1] Maximum depth of 6800m

[2] Depending on the configuration

[3] Maximum depth of 7,000m

[4] In all natural waters, fresh and marine

[5] Maximum depth of 1,200m

[6] Maximum depth of 1,000m

[7] Maximum depth of 6,000m

Methods

Due the continuation of the ice program and heavy ice conditions at the start of the leg, the rosette was deployed from the moonpool for the first portion of the leg and switched to boat deck operations at the mid leg scientific crew exchange. A set of open water stations was also visited throughout the entire leg. CTD or Rosette casts were usually performed four times a day while stationed in the ice at 07h00, 11h00, 15h00 and 19h00. Once, a 13-hour, hourly CTD sampling has been done. Water was sampled according to each team requests. Here are examples of usual depths collected.

- *Nutrients* (Team 7; PI: Jean-Éric Tremblay): salinity of 33.1, chlorophyll maximum, 10, 20, 30, 40, 50, 60, 80, 100, 120, 140, 160, 180, 200, 250, 300 and every 100 m up to the bottom.
- *DIC* (Team 6; PI: Lisa Miller): salinity of 33.1, 5, 10, 20, 30, 40, 50, 60, 80, 100, 120, 140, 160, 180, 200, 250, 300 and every 100 m up to the bottom.
- *Mercury*(Team 8; PI: Gary Stern): salinity of 33.1, 5, 10, 20, 30, 40, 50, 60, 80, 100, 120, 140, 160, 180, 200, 250, 300 and every 100 m up to the bottom.
- *DOC/DON* (Team 7; PI: Christine Michel): salinity of 33.1, 5, 10, 20, 30, 40, 50, 60, 80, 100, 120, 140, 160, 180, 200, 250, 300 and every 100 m up to the bottom.
- *Contaminants* (Team 8; PI: Gary Stern): chlorophyll maximum, 10, 25, 50 m and every 50 m up to the bottom.
- *DNA* (Team 7; PI: Connie Lovejoy)
- *Microbes and Virus* (Team 7; PIs: Carlos Pedros and Roxanne Maranger): ñinterestingò features in the O_2, NO_3, fluorescence, temperature and salinity profiles.
- *CDOM* (Team 3 ; PI: Pierre Larouche): 10, 25 m and chlorophyll maximum while in the ice and 50%, 20% of light, chlorophyll maximum and 60 m while in open water.
- *Pigment* (Team 3; PI: Suzanne Roy): 10, 25 m and chlorophyll maximum while in the ice and 50%, 15% of light and chlorophyll maximum while in open water.
- *Primary production* (Team 3; PI: Michel Gosselin): 10, 25 m and chlorophyll maximum while in the ice and 50%, 30%, 15%, 5%, 1%, 0.2% of light, chlorophyll maximum, 75 and 100 m while in open water.

Sampling locations

During leg 9, our focus was on the Amundsen Gulf, Franklin and Darnley Bay, the MacKenzie river and west and north of Banks island.

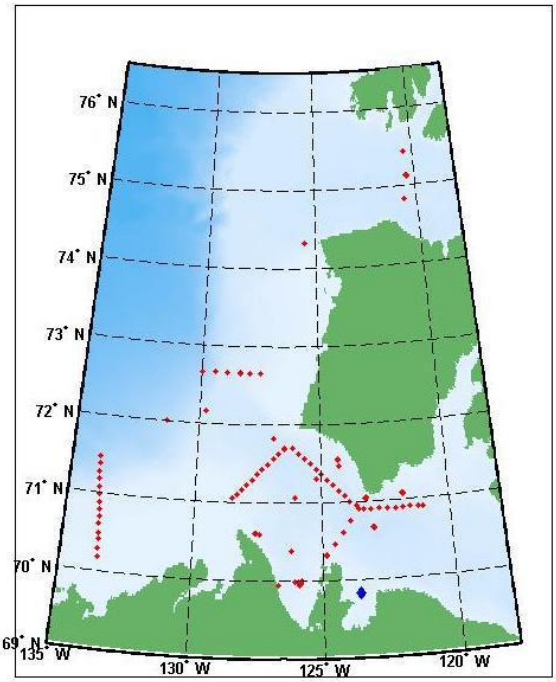

Figure 1: Positions of Rosette casts are shown as red dots and station of 13 hours sampling is blue diamond.

Probes calibration

Salinity: Samples were taken on many casts with small bottles of 200 mL. They were analysed with an autosal GuildLine, model 8400B. Its range goes from 0.005 to 42 and its accuracy is < 0.002. The results were satisfying. The difference between the salinity probe recordings and the samples was around 0.07. A few samples were very dissimilar (by almost 2), but this may be because they have been contaminated during sampling.

pH: Tests were done twice using two buffers.
The sensor is quite stable. Results are as follow:
Buffer 4.01 gave 4.23 and 4.25
Buffer 7.00 gave 7.42 and 7.51
Sea water is usually around pH=8, we can expect pH data to be a little over estimated.

Oxygen: Oxygen sensor calibration was performed using Winklerôs method and a Mettler Toledo titration machine. Reagent Blanks was performed once, results show that chemicals are still good (m<4). Oxygen have been sampled on six casts. Each time, we choose five depths of different oxygen concentration and sampled it three times. The results are not satisfying; the slope of comparison between the sensor and the samples was varying from 0.89 to 0.96. To rectify this problem, we changed the sensor between casts 117 and 118. However, after the change the slope of comparison was still unsatisfactory ranging from 0.85 to 0.91 which led us to surmise that the error could come from the titration machine or the chemical product used. A deeper investigation will be done on next leg.

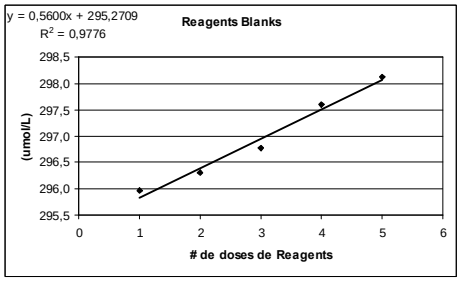

Figure 2: Reagents Blanks (m=0.56) measured during leg 0803 with the same chemicals on cast 061.

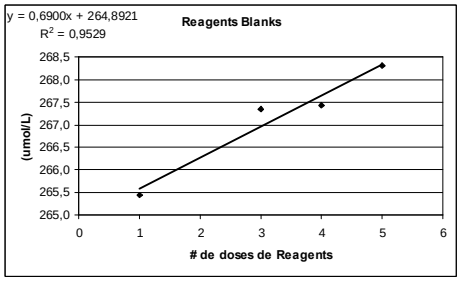

Figure 3: Reagents Blanks (m=0.69) measured on cast 148.

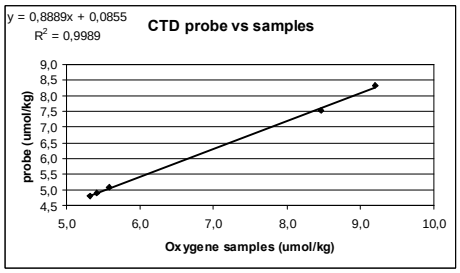

Figure 4: Relation between samples and probe recordings during cast #078 (m=0.8889).

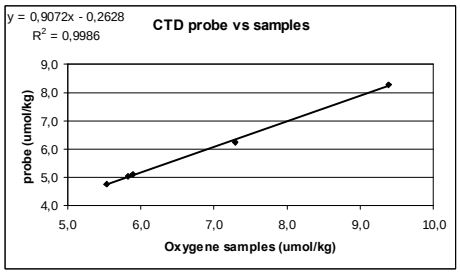

Figure 5: Relation between samples and probe recordings during cast #180 (m=0.9072).

Problems

- **Sensors**
  We had problems with the nitrates sensor for the first few casts after the rosette was moved from the moonpool to the boat deck.
  The oxygen probe may have an offset, it has been changed for a probe that has been calibrated on April 26th 2008 and the difference between Winklerôs method measures and the sensor was still present. Consequently, the problem could come from the sampling or the titration of oxygen.
- **Deck material (winch, A-frame, etc.)**
  The winch on the open deck overheated. Attaching an additional cooling hose rectified this problem.
- **ADCP**
  The currents were only measured sporadically during the leg. The ADCP could not determine the middle range of the water column currents for a still unknown reason. The ADCP also stopped receiving information a few times due to ice under the ship blocking the signal.

Available data

All information concerning the Rosette casts are summarized in the CTD Logbook. It includes cast and station numbers, date and time of sampling in UTC, latitude and longitude, bottom and cast depths, as well as the cast name and comments concerning the cast. A Rosette sheet was also created for every single cast. Information on this sheet includes the type of parameter sampled and weather information. For every cast, data recorded at the moment of bottle closure were averaged and recorded in the so-called ôbottle filesô. Averaged data are those recorded between 3 seconds before bottle closure and 7 seconds after the closure. It includes the bottle number, time and date, pressure, temperature, salinity, transmissivity, chlorophyll, oxygen, irradiance and pH measurements. All those files are available on the ôSharesô.

- Rosette sheets and the CTD logbook : Shares\Leg9\Rosette_CTD\logs
- Bottles files : Shares\Leg9\Rosette_CTD\bottle_data
- Plots of every cast including salinity, temperature, oxygen, transmissometer, nutrients, fluorometer and irradiance : Shares\Leg9\Rosette_CTD\plots

A total of 180 casts were performed between June 5th, 2008 and July 17th, 2008.

Preliminary Results
The ñ13 hour marathonsò were performed at station F7 from the moonpool.

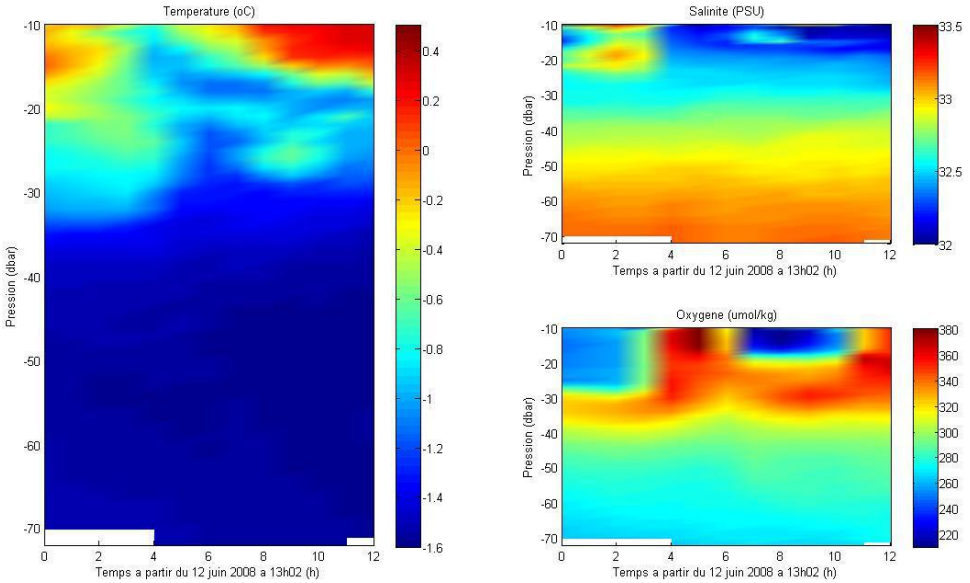

Figure 6: Temperature, salinity and oxygen data recorded on the 13 hour sampling done on station 2008-F7 on June 12th.

Self Contained Autonomous MicroProfiler (SCAMP)

Unfortunately the SCAMP was out of commission in leg 9.

MVP (Moving Vehicle Profiler)

The Moving Vehicle Profiler (MVP) is basically a towed CTD (with fluorescence and dissolved oxygen sensors). It was removed from its winter storage and used first as a CTD (ship stopped) in Darnley and Franklin Bays to provide profiles of the first 10 meters of the water column. The objective was to obtain a section of the Horton River plume (Franklin Bay) perpendicular to the ice edge. When the MVP is used in automatic profile mode, we loose the first 10 and last 10 meters. After the rosette operations were moved to the outside location, it was used in the towed mode only. Figure 7 gives an overview of the MVP sections / profiles in CFL leg 9 (cruise 0804).

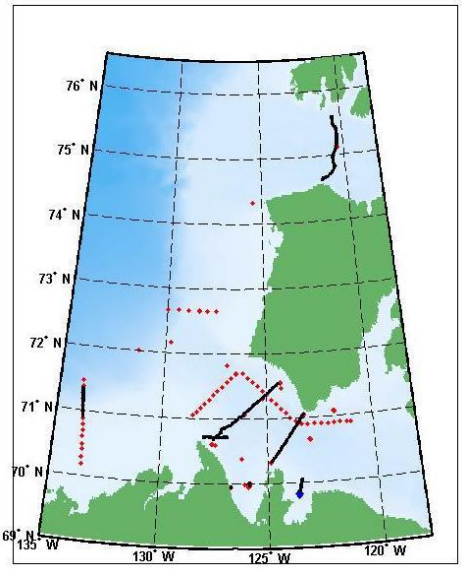

Figure 7: Positions of MVP casts and transects are shown as black dots and lines and rosette stations are shown as red dots.

Problems

Along the MacKenzie transect, the amplitude of surface waves created some difficulty to catch the bottom depth with the EK60 which forced the MVP to end a cast and recover as an automatic security. Thus, the data for this transect had sporadic maximum depths.

Preliminary Results

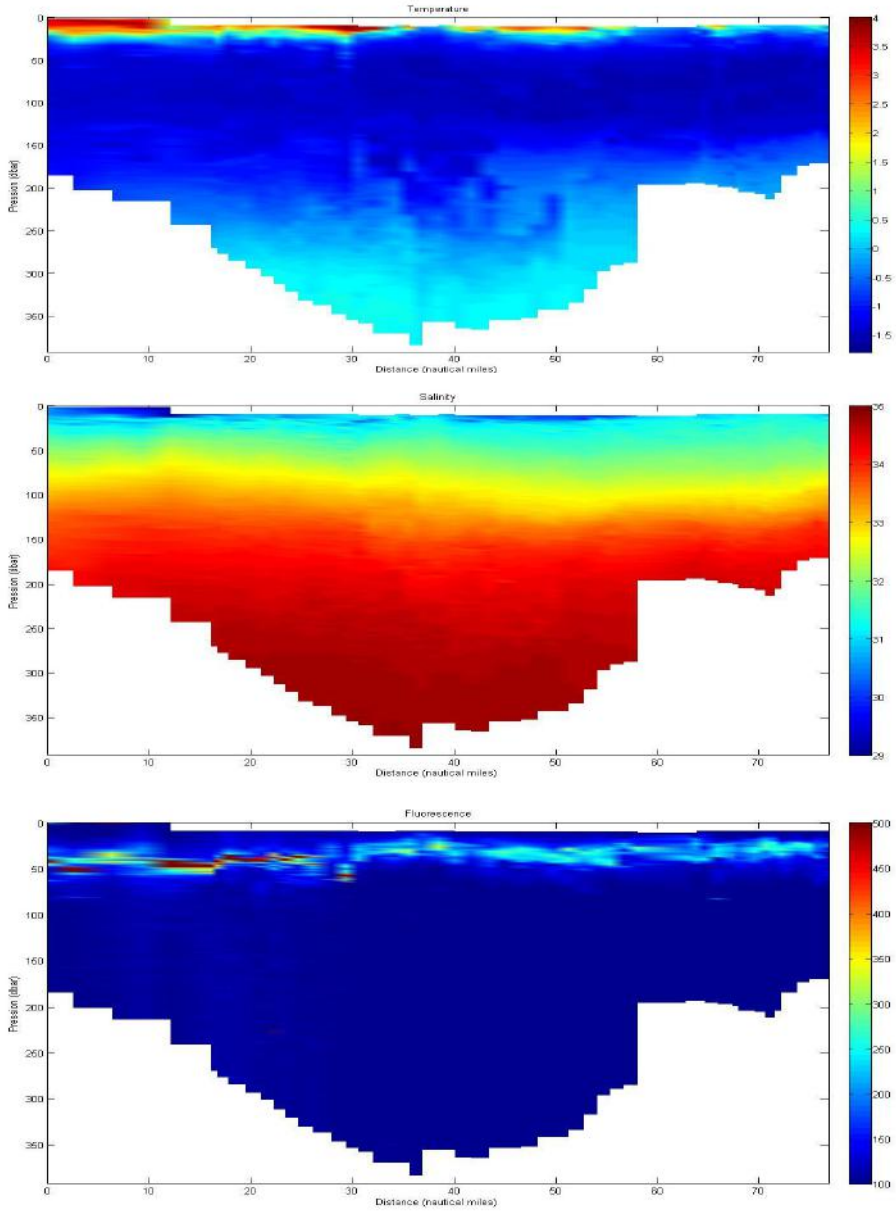

Figure 8: Temperature, salinity and fluorescence data recorded on the MVP transect done along line 1200, across the Amundsen Gulf.

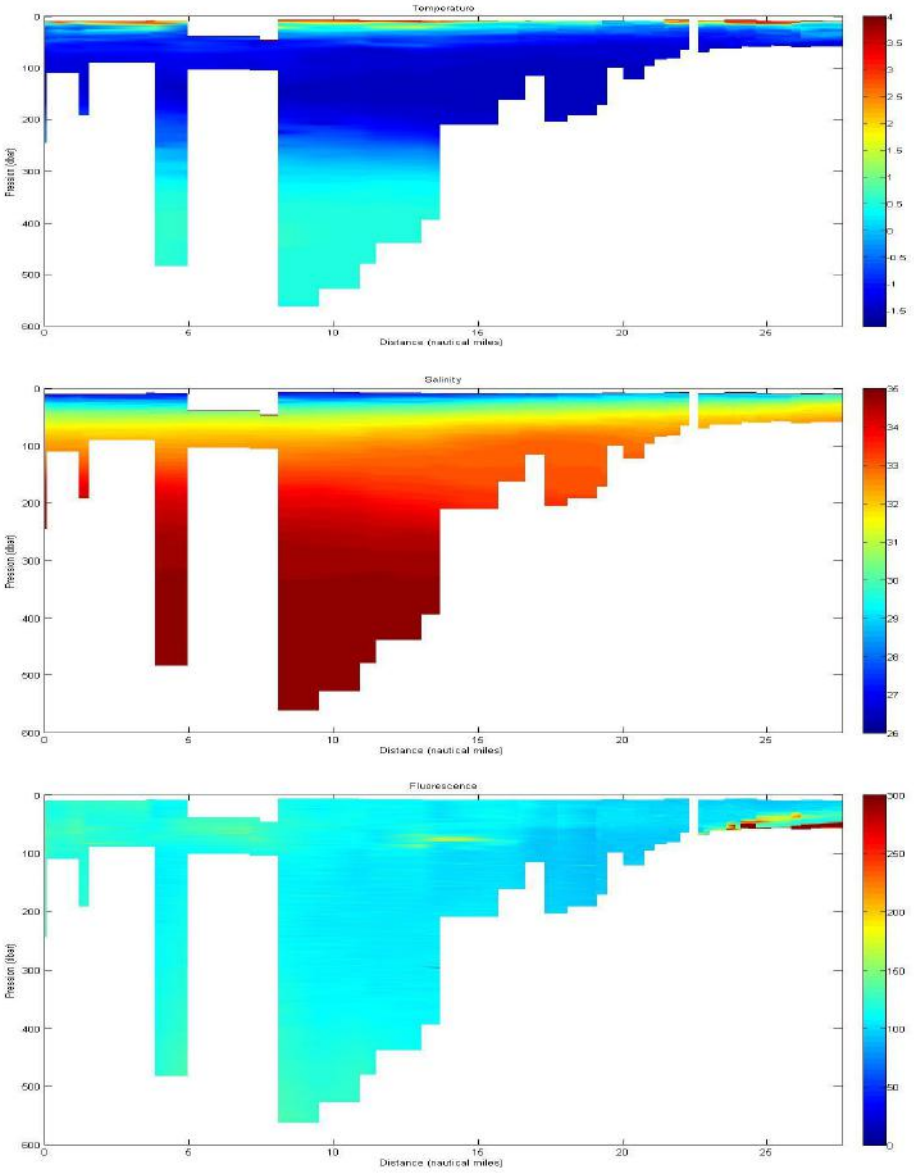

Figure 9: Temperature, salinity and fluorescence data recorded along the MVP transect done between stations 423 and 428, perpendicular to the MacKenzie River at the shelf break.

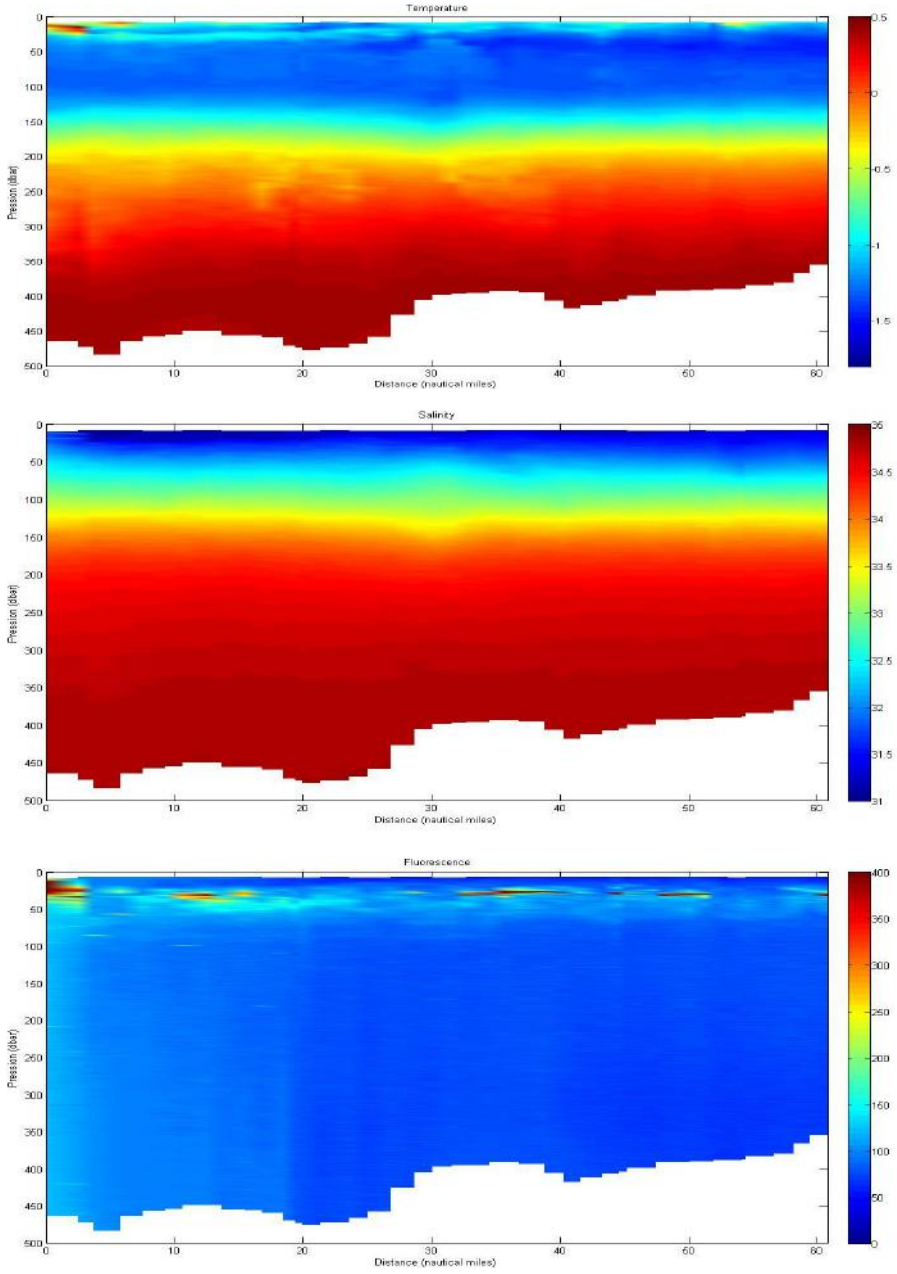

Figure 10: Temperature, salinity and fluorescence data recorded along the MVP transect done between stations 2005 and 2015, across McClure Strait.

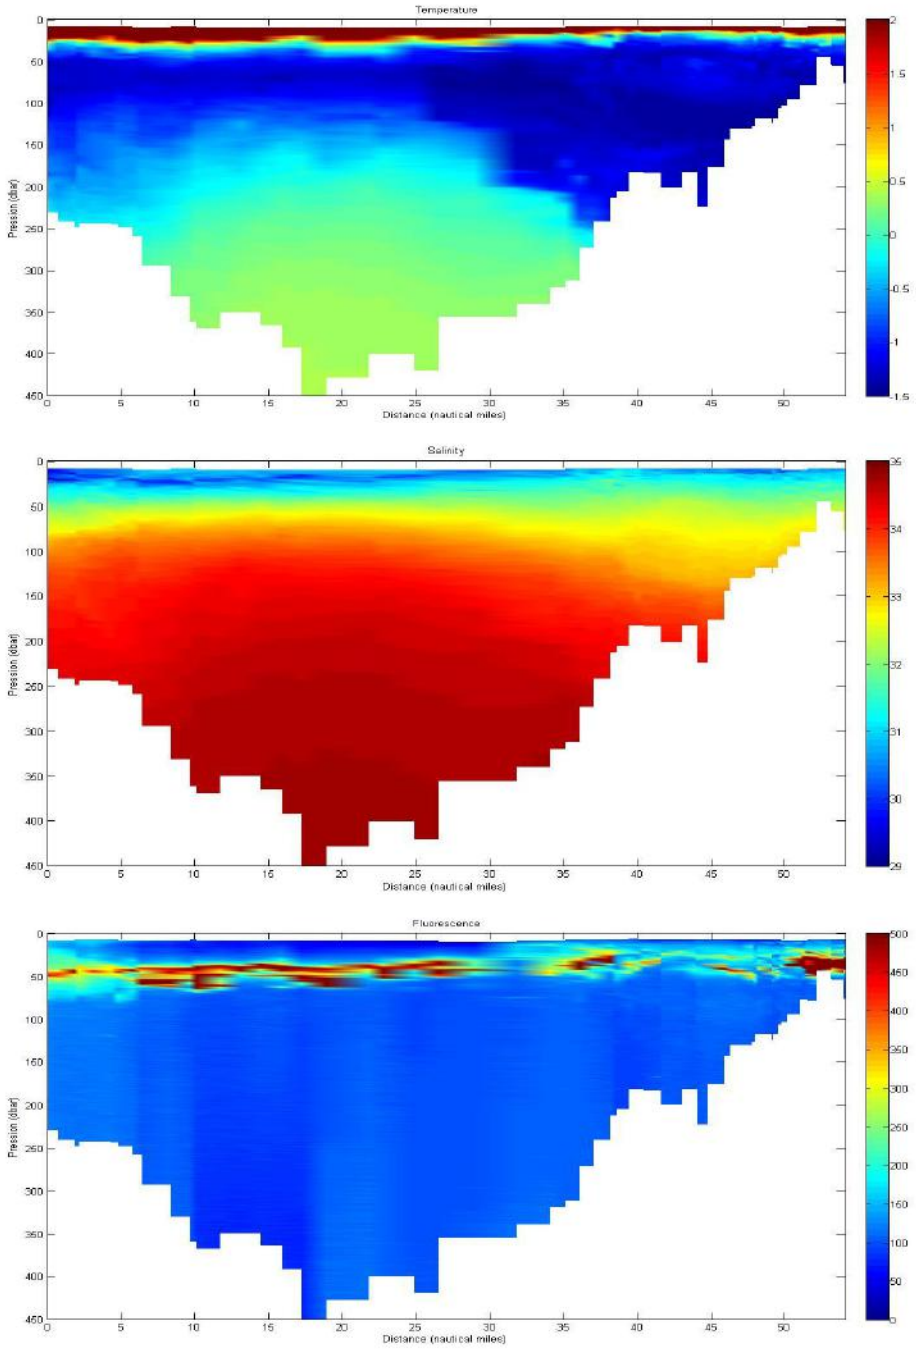

Figure 11: Temperature, salinity and fluorescence data recorded on the MVP transect done along line 1100 between stations 1100 and 1110, across the Amundsen Gulf.

Ice Camp

No long-term turbulence ice camp was deployed due to the poor ice conditions.

Moonpool operations

Moonpool operations were conducted until June 22nd. After that date, the rosette was operated from the outside, starboard ñshackò.

Open water operations

Open water operations began on June 23rd at Full Station 1216 (cast 063).

2.2. Team 2

PI: David Barber (CEOS, University of Manitoba)
Participants: (leg 9A): Klaus Hochheim (Research Associate, CEOS, University of Manitoba), Andrea Rossnagel (MSc Student, CEOS, University of Manitoba), Randy Scharien (PhD Student, CEOS, University of Manitoba/University of Calgary), Mukesh Gupta (PhD Student, CEOS, University of Manitoba), Jens Ehn (Post Doc, CEOS, University of Manitoba); (leg 9B): Mukesh Gupta (PhD Student, CEOS, University of Manitoba), Zhihua Chen (Masterôs Student, Ocean University of China), Shaojun Zheng (PhD Student, Ocean University of China)

2.2.1. Ice Dynamics

Centre for Earth Observation Science (CEOS)
University of Manitoba, Winnipeg

Colored Dissolved Organic Matter (CDOM), Fluorescence of Dissolved Organic Matter (FDOM), Salinity and Oxygen Isotope (δ18O)

Dissolved organic matter (DOM) plays a major role in the ocean as carbon and energy sources for the microbial food web, and for consumers at higher trophic levels that feed on microbes or on DOM directly. The coloured fraction of this dissolved organic matter is a complex pool of autochthonous materials, derived from in situ photosynthetic activity and processed microbially, and allochthonous materials, that are rich in humic substances and largely derived from terrestrial environments.

Fig.1. CDOM sampling

This coloured dissolved organic matter (CDOM) is photochemically active and also influences the spectral underwater regime that in turn affects primary production. The composition and reactivity of CDOM in aquatic ecosystems are still poorly understood. The sources and dynamics of DOM are of special interest in the coastal Arctic Ocean. These environments receive inputs of freshwater from large rivers that drain arctic tundra and peatlands as well as subarctic boreal forest. To increase the understanding of this tracer we are coupling the sampling with $\delta^{18}O$ which is a conservative tracer of freshwater masses. It has been estimated that more than 25% of the worldôs soil carbon lies in these catchments, and there is concern about how ongoing climate change may mobilize these stocks and transport them to arctic seas. The carbon derived from arctic rivers appears to be a major source of terrigenous DOM to the deep ocean, and changes in the magnitude and composition of this material therefore have broader oceanographic implications.

Global circulation models predict that the arctic basin will experience greater and more rapid warming than elsewhere over the course of this century, and there is increasing evidence that global climate change has already begun to have significant impacts on permafrost degradation and terrestrial vegetation dynamics at high northern latitudes.

Water was collected onboard using the rosette from the moonpool and off the ship from the zodiac.

Due to problems with the spectrophotometer Cary 50, the CDOM samples were stored at 4^{o}C and measurements of CDOM will be completed at University of Manitoba.

Preliminary Results:
CDOM and FDOM analysis will be performed after the cruise in laboratories at the University of Manitoba. Stable isotope analysis of water samples will be analyzed outside of the university.

CTD and Optical Measurements
The objectives of this experiment are to examine potential impacts of sea ice (and related environmental parameters) on light intensity under various sea ice, snow and solar zenith angle regimes during the spring transition period (Legs 7, 8b and 9a). To address this objective we will be measuring light fields (PAR) above and under the ice down to 60 m, albedo, snow properties (temperature, grain size, salinity) and upper ocean properties (conductivity and temperature) along with other relevant surface validation data. These measurements will be done in fast ice floes, landfast ice as well as in leads and the marginal ice zone. The ultimate intent is to extrapolate these observations/results to regional scales.

Fig. 2. A CTD and PAR profile through the ice

CTD (Conductivity, Temperature, and Depth) and PAR (Photosynthetically Active Radiation) profiles were done opportunistically with a focus on different snow and ice, and meltpond conditions as well as different times of the day. This is to see the effect of different snow and ice regimes on PAR in the water column below the ice. Profiles were also done through melt ponds, thin ice as well as open water between floes from the skippy boat. Transects from open water to the ice edge and across floes were also done when possible. Sampling was done at different times of the day to see the effect of solar zenith angle.

Snow pits including a vertical pit photo, and snow grain photos, density and salinity were done for the top, middle and bottom of each snow pack when possible.

Table 2. PAR/CTD profile and albedo sample locations.

Snow Pits: T = temperature profile, Cap = capacitance plate, SGA = snow grain analysis, D = density
Dep = Depth
ASD: DW = Downwelling, UW = Upwelling

Fig. 3. Setting up the ASD to collect downwelling irradiance.

Downwelling and upwelling irradiance measurements were done at most ice stations with an extended range radiometer from ASD. If there were different surface types at one site downwelling and upwelling irradiance was measured with the ASD at more than one location for each site.

Two 4 km transects perpendicular to the ice edge were completed on June 12 at F7 in Darnley Bay. One transect was 1 km east of the ship and the other was 1 km west of the ship. There were six sites on each transect and at each site a PAR and CTD profile were done down to 60 m. These transects were completed to look at the melt layer and light in from the ice edge in conjunction with the EM researchers in Team 2.

The Satlantic HyperOCR profiler was used for profiles down to 50 m along the Franklin Bay transect. These were done at FB1, FB1.5 , FB2, FB2.5, FB3, and FB3.5, and FB4.

Dive Program
During the first half of leg 9 there was a dive program that Team 2 was involved in. Team 2 was involved in two parts of the dive program which were a bio-optics dive program in conjunction with Team 3 and an ice edge dive.

During each bio-optics dive, measurements were made in a north-south transect under the ice every meter starting under a snow area then under a melt pond and then under the snow on the other side of the pond. These optical measurements were made with the Satlantic HyperOCR hyperspectral radiometer. It has 255 channels with wavelengths ranging from 300 to 1200 nm and integrates Wet Labs ECO series sensors which include sensors to measure concurrent conductivity, temperature, pressure, chlorophyll fluorescence and optical backscattering. At the end of each transect the diver dropped the profiler and a profile down to 50 m was completed. A rope was tied from the starting point to the end above the ice and below. Measurements of the distance from the rope to the upper surface and rope to the bottom of the ice were made along with pond depth and snow depth at each meter where the optical measurements had been made. When the optical measurements were made, the diver wore a re-breather to reduce the amount of bubbles.

Table 3. Bio-optics dive locations.

Date (mm-dd-yyyy)	Station (#)

18/06/08	F7
20/06/08	FB7
21/06/08	FB7

During the dive program Team 2 also led an ice edge dive. These dives were to investigate the differences in light from the open water to the ice edge and then from the ice edge under the ice. The profiler was carried by the diver along a transect and was also dropped for a profile down to 50 m under the ice and in the open water by the ice. The surface along the dive transect was characterized.

Ice physical-microstructure (Ice Raid)

General ice conditions:
During first half of Leg 9 we encountered FYI melt ponds and snow patches frequently mainly in Darnley Bay and Franklin Bay. The ice was ablating and breaking up at a rapid rate during this time period. By the end of Leg 9A, there was no fast ice left, though there were small ice floes around. Leg 9B was conducted in open waters except for a single stop in MðClure Strait where we were able to sample the fast ice on July 6. Therefore, the ice raids pertain to fast ice in Darnley Bay, Franklin Bay and MðClure Strait.

Physical sampling:
A field program (Ice Raid) was designed to obtain the physical-microstructure properties of sea ice. To access the ice surface during Leg 9, we landed on ice, lowered from the starboard and port side of the ship by gangway and sometimes by crane. Air and ice temperatures were measured by a hand-held temperature probe.

Ice surface condition (i.e., snow patches, melt ponds, thaw holes) was recorded. We took ice cores: one for temperature measurement, a second was cut in 10 cm pieces and put into whirlpack bags for the salinity measurement, and a third core was taken for micro-structure. At all stations, the ice thickness was found to be more than 1 m. Each 10 cm piece of ice core was melted to room temperature before measuring the salinity using a conductivity meter.

We set up the cold lab (-20°C) to take ice microstructure photography including thick and thin sections. We note the temperature of the cold lab varied between -11°C and -20°C, but occasionally increased up to -8.0°C. The temperature in the lab sometimes fell to -23 degrees. To take thick section (5 mm) photography, we cut an ice core into pieces and attached the piece on a glass plate, and fixed the ice piece by applying three layers of freshwater around the piece. Once, the ice piece firmly fixed on the plate, we prepared a thick section by shaving down the ice piece to about 5-10 mm thick using Bandsaw and Microtome. Then, we took pictures of the thick section by a digital camera (Canon, PowerShot G2) to see air bubble or brine pocket/tube distribution. Once thick section pictures were taken, we shaved down the ice piece to a millimeter thick (called a thin section). Then, we took cross- and parallel-polarization images from the thin section by putting polarized sheets under the ice section and between the ice section and the digital camera.

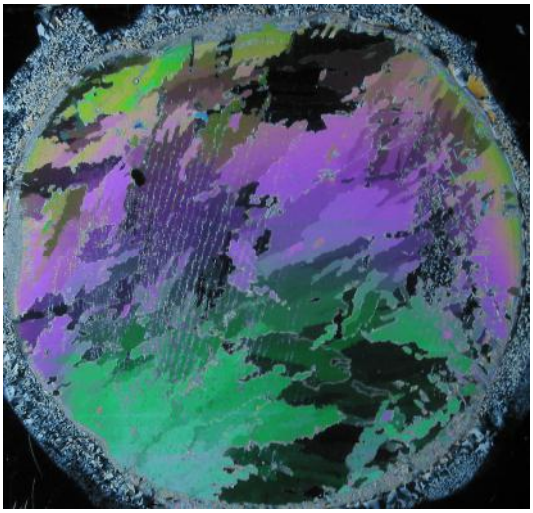

Fig. 4. Horizontal cross-polarized ice microstructure (130-140 cm) from MõClure Strait on July 6, 2008.

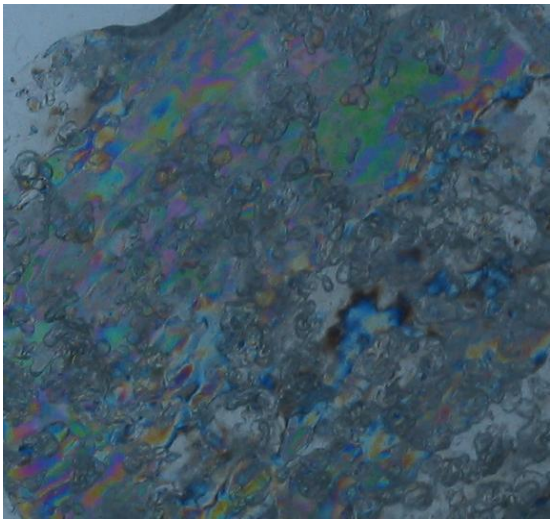

Fig. 5. Vertical co-polarized ice microstructure (0-10 cm) on June 13, 2008.

Sometimes we faced the difficulty in fixing the ice core onto the glass plate which made it difficult to make 1 mm sections. Therefore, some of the sections are 1.5 to 2 mm thick. Horizontal microstructure picture were also taken for MõClure Strait fast ice.

The light table stopped functioning at the end of Leg 9A. We used external flash light to illuminate light table. This brought difficulty in maintaining proper light conditions in the pictures.

Surface EM measurements

Objectives:
Ship-based ice-EM measurements were conducted to investigate the interactions between microwave signatures (both active and passive) and sea ice thermo-physical properties. The observed data will be used to calibrate sea-ice products from the satellite sensors and to evaluate the theoretical microwave emission/scattering models. This result will provide more advanced knowledge of how microwave signature reacts to the evolution of sea ice thermo-physical properties on small scales during the fall freeze-up period.

Instrumentation and methods:

The radiometers are dual polarized (vertical and horizontal) radiometers at 37 and 89 GHz with 6° beamwidth antennas (Radiometrics). The radiometers were mounted about 12 m above the sea surface on the portside of the ship. During transect, the radiometers were fixed at the incident angle of 55°. Whenever the ship was stationary, we changed the incident angle of the radiometers from 30° to 150° at a 5° interval. The SBR position stopped functioning since June 24th; therefore data was acquired only in fixed mode at 55 degree elevation angle. On July 12 the UPS battery in the SBR box died, therefore no SBR data is available between July 12 and July 17 (Crew change). A network camera (Cannon, VB-C10R) was mounted on a rail right beside the wheelhouse. The initial set-up for the camera was pan=0.00°, tilt=-25.00° and zoom=43.40° and was changed to tilt=-40.00° from Nov. 1. The pictures were taken every 10 sec to 1 min depending on surface conditions. A hand-held digital camera was also used to record the visual surface condition.

A C-band polarmetric (VV, VH, HV, HH) scattereometer system (PROSENSING) was deployed about 7.56 m above the sea surface (Figure 6). Whenever the ship was stationary, measurements from the ship were done from -30° to 30° in the azimuth, with the 0° reference at a perpendicular line to the ship side and from 20° to 60° in elevation at 5° increment. An infrared transducer (Everest, 4000L) was mounted on a rail in the shed for the C-band scattereometer system (Figure 6). Ice thickness camera was set up on the main deck at the port side. The scatterometer positioner from University of Calgary was used after June 26th onwards and data was acquired as originally planned.

Infrared Transducer back up was taken on weekly basis. At a couple of occasions the instrument was taken off for Beluga surveys.

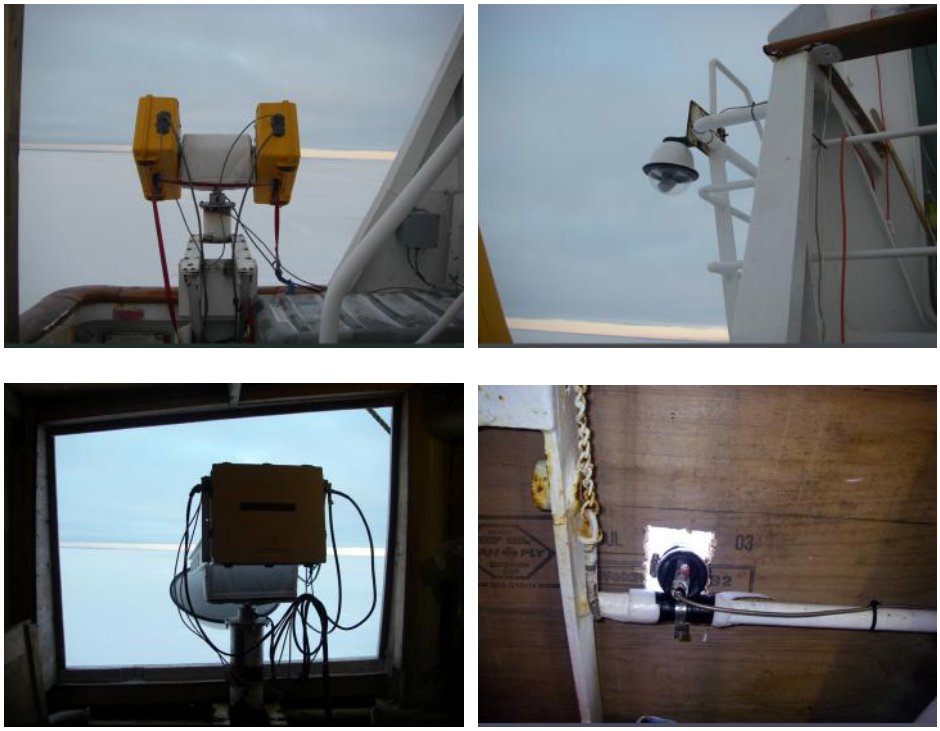

Fig. 6. Microwave radiometer system (top left), webcam (top right), scatterometer (bottom left) and infrared transducer (bottom right).

Meteorological Ocean Buoy (MOB)

The Meteorological Ocean Buoy (MOB) is comprised of a Data Well DWR-G4 buoy, modified to provide the additional functionality of a wind speed and direction sensor and an RF locating beacon. The Datawell DWG-4 buoy acquires and logs wave height data from a stabilized accelerometer, and wave direction data derived from GPS signals. To supplement this data, a number of additional parameters are collected and logged by the Metocean electronics (Metocean stack).

The Metocean stack includes an Ultrasonic Wind Sensor and a TCM2 compass that accurately measures the compass heading, buoy pitch and roll. Metocean stack also measures the battery voltage of the battery pack.

While the Datawell stack logs data into a flash card on the data logger on its stack, in order to store results from the Metocean Sensor stack, a second flash card is used with the Persistor CF-1 CompactFlash® datalogger module as part of the Metocean stack. Data from these flash cards can be saved on a hard drive independently and decoded using Metocean and datawell supplied decoding programs.

Once activated, the battery pack provides 25 days of continuous operation of the buoy. The Metocean stack samples various sensors connected to it once every 15 minutes and logs the results accordingly.

Deployment:
The buoy was deployed at every full station for minimum of 2 hours and maximum of 15 hours. It was deployed most of the time by zodiac 100 m away from the ship. At many occasions it was deployed by line from the front deck. Help from the crew in deployment and recuperation is highly appreciated. Once it was deployed using the barge.

Recuperation:
The buoy was recovered using either the zodiac, cage or barge. The ship heading and buoy bearing on ship DF was matched and the ship was sailed towards the buoy and a team with binoculars started finding the little yellow dot right in front of the ship. As soon as the buoy was spotted, the zodiac was deployed to retrieve it. This operation was done whenever the buoy was invisible and drifted quite far from the point of deployment otherwise only the zodiac was deployed with direction instructions on wireless to find the buoy.

Fig. 7. Meteorological Ocean Buoy (MOB) deployment by line (left) and data acquisition (right).

Data acquired:

Preliminary results:

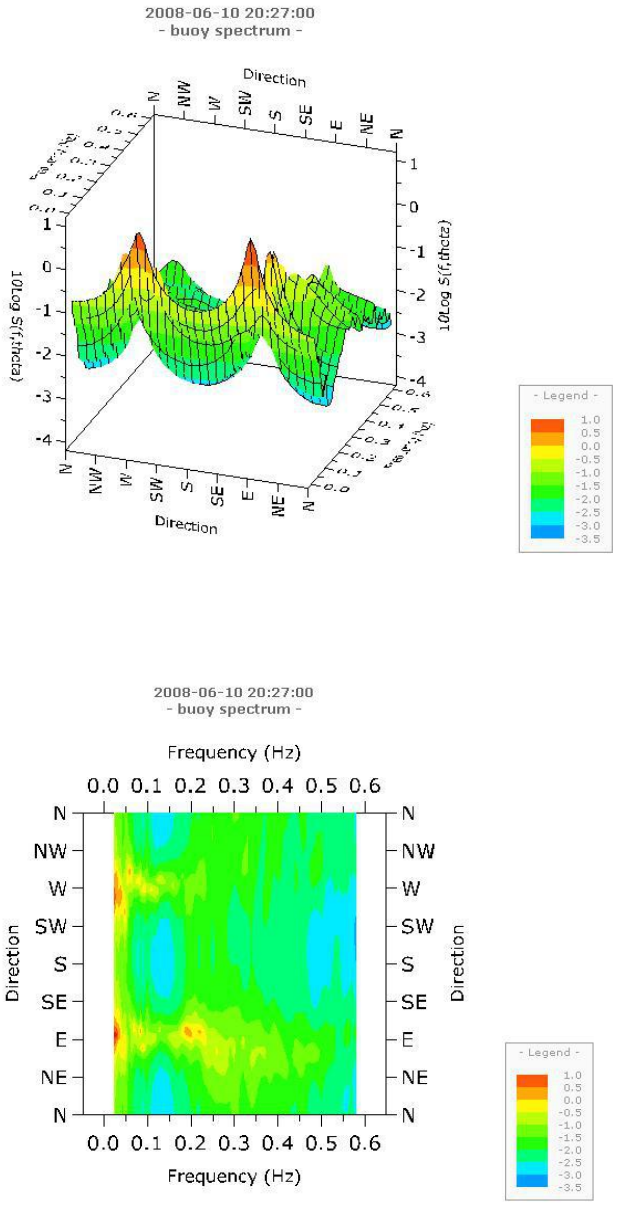

Fig. 8. MOB spectrum preliminary results.

Performance of buoys:
The buoy worked very well during most of the deployments; however, the radio beacon did not work a couple of times. The buoy was recuperated using zodiac with a hand held DF. High quality DF on ship was also used in parallel to track the buoy.

Vaisala wind sensors record data quite irregularly. Therefore, the surface wind data is not available for many stations. The reason behind the irregular functioning of wind sensor is as of yet unknown.

Laser Wave Slope (LAWAS)

Lawas was operated at every station when ship was at stop and sometimes during motion. At the fast ice stations the LAWAS data over melt pond waves was also acquired. At fast ice stations LAWAS was used as a mobile laser profiler to walk on the snow patch and melt pond in series.

Deployment:
LAWAS was deployed on fast ice melt ponds using tetra pods (Fig. 9) to measure the waves in the melt ponds and roughness over the snow patches. It was also used in profiling mode over the snow patches and melt ponds with two persons holding the system and one person towing the unit from behind. For all open water stations, the LAWAS was deployed on the foredeck on the beam (see picture).

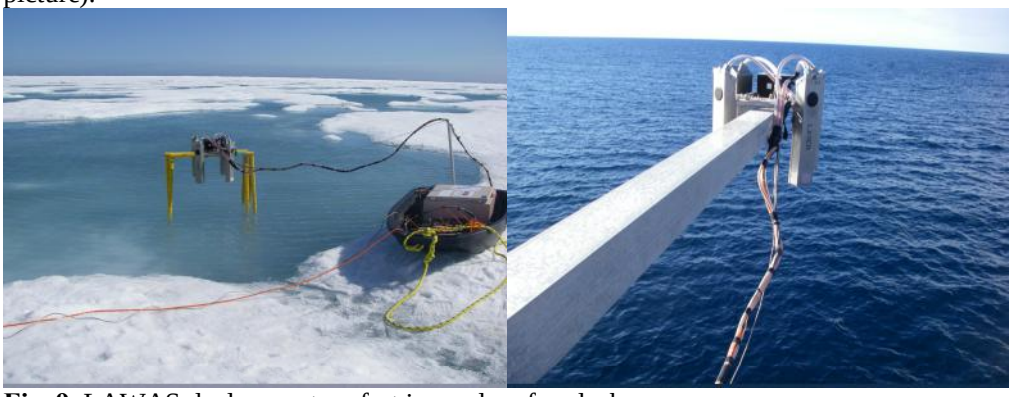

Fig. 9. LAWAS deployment on fast ice and on foredeck.

The wind direction was noted at every deployment and picture of the wind tower was taken every time.

Beluga Surveys

During the Leg 9A, extensive Beluga surveys were conducted. The surveys were conducted using the helicopter and charter planes (Fig. 11). The video shooting of Beluga whales was also made. A few surveys were done near the fast ice edge in the Darnley and Franklin bays.

Fig. 11. Beluga whales observed from the helicopter.

2.2.2. Optical Observation

By Shaojun Zheng and Zhihua Chen

Key Lab for Polar Oceanography and Global Ocean Change
Ocean University of China

Ocean Profiler II

Purpose:

The Profiler II design builds on the experience gained by Satlantic on previous generations of profiling instruments. It offers researchers the unique opportunity to use the system as a free-fall profiling device or in conjunction with a detachable float for near-surface measurements. The system is also available mounted on a lowering frame.

The Profiler II is specifically designed to allow the interchangeable use of Satlanticôs high-resolution multispectral OCR-500 series optical sensors and hyperspectral HOCR (or OCR-3000) sensors1. Optional features include a conductivity sensor and integration of up to two non-Satlantic instruments into the instrument package, making this system the most versatile platform for measuring the apparent optical properties of the ocean. The system addresses the issues of self-shadowing and ship induced disturbances while offering a wide dynamic range in an easy to deploy package.

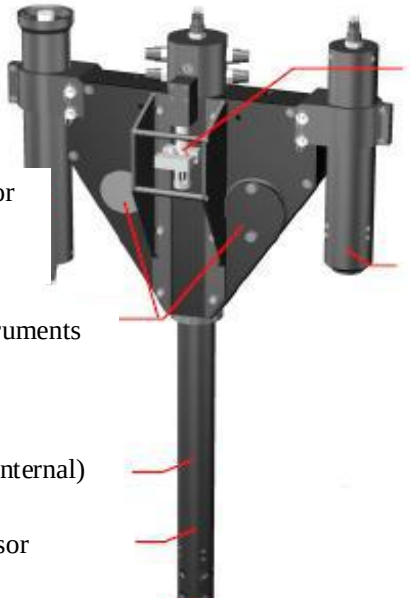
Background:

The Profiler II is Satlanticôs next-generation profiling instrument, building upon the very successful MicroPro design. The primary goal of this design was to allow data to be collected with a high spatial resolution in the regions around a field station on a typical oceanographic cruise. A secondary goal for the instrument was to support experiments in the case-2 waters that are often found in the nearshore and littoral environments. Water conditions in these areas are such that light levels below 100 meters depth (generally below six optical depths) are extremely low, difficult to measure, and provide little significant information in terms of the satellite validation mission being performed. In addition, attenuation levels are high enough that it becomes important to have downwelling irradiance and upwelling radiance sensors located close to the same depth.

The Profiler II design builds on the experience gained by Satlantic on previous generations of profiling instruments. Designing the Profiler II with the capability to operate in both free-fall and at-surface modes, the ability to interchange hyperspectral and multispectral sensors, and the seamless integration of two foreign sensors such as a fluorometer and backscatter meters, has resulted in an outstanding instrument package.

Instrument:

Profiler II major components:



Reference Sensor:

Cable:

Deployment Procedure (free-fall deployment):
The primary advantage of the free-fall deployment technique is that it provides a straightforward method of making measurements away from a vessel in such a way as to drastically reduce or completely avoid ship induced perturbations. In this way clean passive optical sensor data can be collected.

HyperSAS

Purpose:

The HyperSAS remote sensing system is designed for above-water measurements of ocean color using Satlanticôs OCR-3000 (MiniSpec) series of digital optical sensors. The primary purpose of the HyperSAS is to allow the user to obtain high-precision, high-resolution hyperspectral measurements of water-leaving spectral radiance and downwelling spectral irradiance.

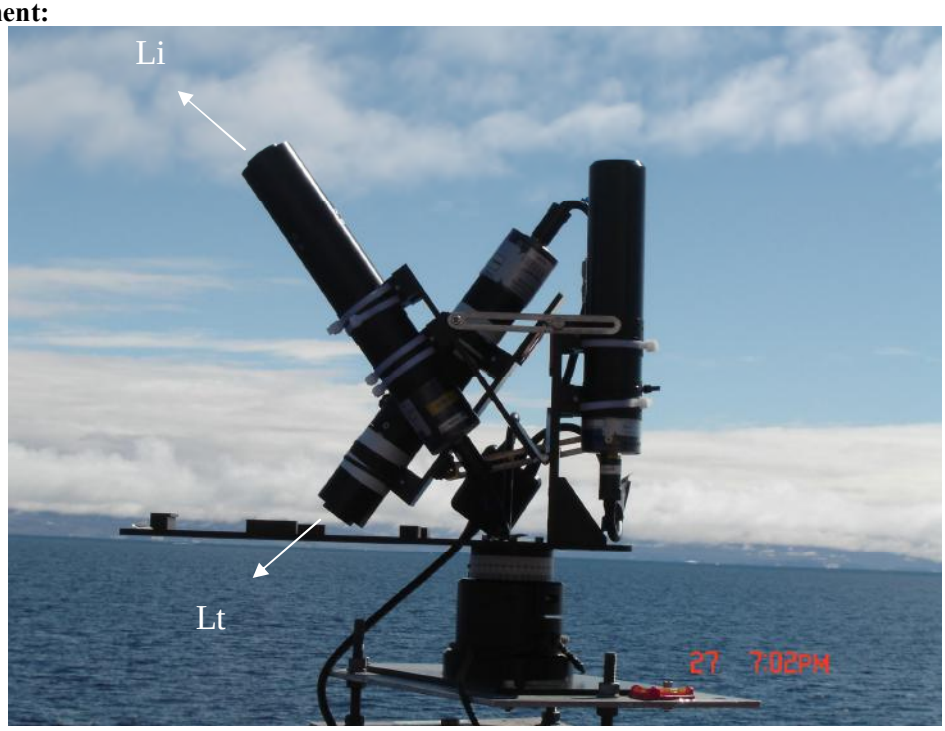
Background:

The HyperSAS system normally consists of two radiance sensors and one irradiance sensor. One radiance sensor is pointed to the ocean to measure the sea surface signal (LT), while the other (Li) is pointed to the sky to provide information necessary for sea-surface glint correction. The irradiance sensor (Es) is used to monitor the downwelling light field and is required for computing remote sensing reflectance.

The HyperSAS can be mounted on a variety of vessels to provide continuous monitoring of ocean color along the shipôs track, on towers or other platforms to provide time series observations, or on aircraft to allow airborne remote sensing of ocean color. The system is small, light, and compact, making it very easy to deploy.

The spectral water-leaving radiance and remote sensing reflectance obtained from HyperSAS data are used to derive the concentrations of sea-water constituents such as dissolved organic matter, suspended sediments, and chlorophyll concentration in the surface layer. Since chlorophyll is an indicator of algal biomass, this information is utilized to estimate phytoplankton abundance and marine productivity, to detect phytoplankton blooms, and to monitor organic pollution through its influence on these blooms. The HyperSAS also provides valuable surface truth for calibration and validation of satellite ocean color products. If surface water samples are obtained simultaneously with HyperSAS measurements, the combined data set can be utilized for biooptical modeling

Instrument:



HyperSAS

Irradiance sensor

Note
The Es or irradiance sensor is a Satlantic OCR-3000 series irradiance sensor. The Es sensor should be mounted high on the ship to minimize errors due to ship shading, stack gases, and so on.

The observation geometry is a crucial part of the SAS measurement protocol. The sea and sky radiance sensors must be pointed at the same nadir and zenith angles respectively. This angle is usually chosen to be between 30° and 50° with an optimum angle of 40°.At this angle the sea surface reflectance for the skylight does not depend greatly on the wind speed and the constant value of 0.028 can be used in sky glint correction. To avoid the direct sun-glint the sensors should be pointed at the azimuth angle between 90° and 180° away from solar plane, with an optimum angle of 135° away from sun. With this orientation the glint effect will be minimized and water-leaving radiance will dominate the total signal.

2.3. Team 3

PI: Michel Gosselin

Participants: C.J. Mundy (Postdoctoral Fellow), Claire Evans (Postdoctoral Fellow), Thomas Brown (PhD student), Eva Alou Font (PhD student), Molly Palmer (PhD student), Benoît Philippe (Masters student), Mathieu Ardyna (Masters student), Kevin Randall (Masters Student), Amélie Sallon (Masters student)

Primary producers fuel nearly all of the Earthôs ecosystems by converting the sunôs energy to an available food source through a process called photosynthesis. During photosynthesis, primary producers fix carbon dioxide, an important greenhouse gas, into food molecules connecting them, albeit indirectly, to our global climate. In this project we have focused our efforts to better understand physical (e.g., light) and chemical (e.g., nutrients) factors affecting primary production within the Beaufort Sea and Amundsen Gulf.

In seasonally ice-covered seas, primary producers can be found in two generalized environments (habitats): (1) associated with sea ice (ice algae) and (2) suspended in the upper water column (phytoplankton). The timing, intensity and duration of primary production in these two environments

are different. Both habitats play a very important and integrated role within the ecosystem. In a typical Arctic marine ecosystem, the relative importance of sea ice algae and phytoplankton follow a seasonal progression, with sea ice algae providing an initial food source for heterotrophs in early spring when the region is ice-covered, followed by a shift to phytoplankton production as the ice melts away during summer months. However, in the flaw lead system where open water can exist even in winter, the general location of primary producers is understandably much more complex. Contrasting the environments of primary producers in the flaw lead with the surrounding ice cover is a driving goal of our research. Furthermore, we have not had the opportunity to examine this dynamic region throughout the entire year, until now with the Circumpolar Flaw Lead System Study.

2.3.1. Ecology of algae associated with ablating landfast first-year sea ice

C.J. Mundy
Institut des Sciences de la Mer (ISMER)
Université du Québec à Rimouski (UQAR)
christopher-john.mundy@uqar.qc.ca

Logistical constraints have limited the number of biophysical studies focused on sea ice ablation in the Arctic. The study of the algal community associated with melting sea ice is no exception to this statement. Only a handful of studies exist that examine the ecology of algae associated with ablating sea ice and these studies have largely involved multiyear sea ice. In this project we had the unique opportunity to sample first-year landfast sea ice from the beginning of melt through to break-up in both Franklin and Darnley Bay. It is noted that this sub-project was accomplished in close collaboration with team 2 who focused on physical aspects of the environment.

As melt progresses in sea ice, an intricate surface of melt ponds and ice patches form, while on the bottom surface domes can form beneath melt ponds. The different surfaces of the sea ice in addition to the interior ice matrix were assumed to be different environments for colonization of algae and therefore were each sampled during this study. Figure 1 shows a schematic of melting sea ice depicting the different regions sampled. Regions A through E were obtained via slurp guns and under ice samples were obtained with the assistance of SCUBA divers. Region F was collected via ice core extraction using a 9 cm core barrel (Kovacs© Mark II Coring System). The ice core was further separated into sections starting from the bottom 0-3 cm, 3-10 cm, 10-20 cm and then 20 cm sections until the surface of the ice.

Ice core sections needed to be melted prior to analysis. To minimize osmotic shock, core sections were melted in 0.2 µm filtered seawater (FSW) at a dilution of 100 ml FSW per 1 cm of core prior to melting. Once melted, nutrient (Nut) samples were taken, followed by a measurement of the salinity and total volume of the samples. It is noted that nutrient samples for FSW were collected as well as nutrient samples for additional core sections (i.e., no FSW added) which were stored in whirl-pack bags and placed in darkness to melt. Nut samples were also collected for slurp gun samples.

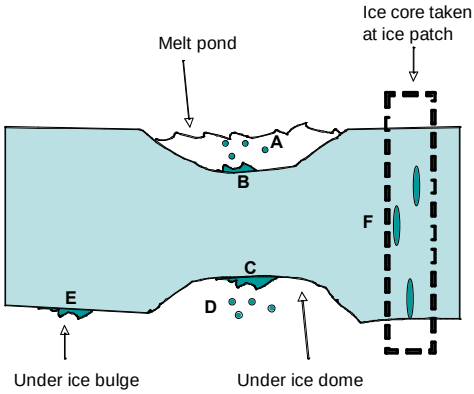

Figure 1. Schematic of the different regions sampled for analsysis. A = meltpond water, B = meltpond bottom surface, C = under ice dome surface, D = under ice dome water, E = under ice bulge surface, F = ice core taken at an ice patch

All water (collected via slurp guns) and melted ice core samples were filtered for determination of size fractionated chlorophyll *a* (chl *a*), particulate organic carbon and nitrogen (POC/N), spectral absorption of particulate matter (Ap), high performance liquid chromatography pigment analysis (HPLC), general cell identification (Cells; fixed in Lugol Acid and Formalin and to be counted via inverted microscopy), cell identification of autotrophs and heterotrophs via epifluorescence microscopy (Epi), and abundance and size class of pico/nanoalgae and bacteria via flow cytometry (Cyto) (Table 1). It is noted that above the bottom 10 cm of the ice core only Chl *a*, Cells, Cyto, Ap and HPLC were analyzed.

The water column under the ice was also sampled coincident with the rest of the data collection. Water was generally sampled from 2, 5, 10 and 25 m depths. The water was analyzed for Chl *a*, Nuts, Cells and Cyto. However, an intense under-ice bloom was observed in Darnley Bay (Sta. F7) on 11 to 18 June, 2008 and therefore, more depths were sampled and are included in the next section on ñphytoplankton communityò.

Table 1. Data collection locations sampled during leg 9.

Station	Date	Location	Latitude (N)	Longitude (W)

2.3.2. Phytoplankton Community

Benoît Philippe, Mathieu Ardyna, C.J. Mundy, Amélie Sallon
Institut des Sciences de la Mer (ISMER)
Université du Québec à Rimouski (UQAR)

Kevin Randall
Université Laval

Phytoplankton, referring to algae suspended in the water column, represent the major primary food source of the oceanic food web. Growth largely depends upon access to light or nutrients. Light profiles of the water column were conducted with a Natural Fluorescence profiler (PNF 300) and the atmosphere irradiance with a Li-cor quantum sensor. The water samples were collected with niskin bottles mounted on a CTD (conductivity, Temperature, Depth) rosette. Seven optical depths were sampled (100%, 50%, 30%, 15%, 5%, 1% and 0.2%), and 75m, 100m, 200m, 400m and maximum chlorophyll were also sampled when available.

Samples were filtered for size fractionated chlorophyll *a* (chl *a*) (>0.7 µm, >5 µm and >20µm), particulate organic carbon and nitrogen (POC/N), dissolved organic carbon and total organic carbon (TOC/DOC), high performance liquid chromatography pigment analysis (HPLC), general cell identification (cells fixed in Lugol Acid and Formalin and to be counted via inverted microscopy), abundance and size class of pico/nanoalgae and bacteria via flow cytometry (Cyto).

During leg 9B we were able to collect 11 samples for determination of size fractioned (>0.7 εm and >5 εm) primary production to estimate daily primary production at 7 photic depths (depths corresponding to 100%, 50%, 30%, 15%, 5%, 1%, and 0.2% of the surface irradiance) following JGOFS protocol for simulated in situ incubation. A radioactive tracer (Carbon 14) was used to determine the phytoplankton carbon uptake rate. An incubator installed on the foredeck was used to control the different environmental light conditions with different filters wrapping plexiglass tubes, one for each depth. The major issue was the temperature of the incubator, which was fluctuating a lot

and was always 5 degrees Celsius above the surface temperature of the Arctic Ocean. The main purpose of this incubator was to create the same environmental conditions found in the water column for *in situ* experiments.

Table 2. Number of depths sampled for each variable collected from the rosette during open water casts.

2.3.3. Ice Algae Biomarkers

(Thomas Brown)
University of Plymouth
thomas.brown@plymouth.ac.uk

Objective:
An investigation into the use of compound specific biomarkers from sea ice diatoms to determine the presence of past Arctic sea ice.

Background:
Previously, the Plymouth team (Guillaume Masse, Simon Belt, Lindsay Vare and Thomas Brown) have demonstrated that an unusual chemical biomarker, derived from sea ice diatoms, can be detected in sediments below sea ice, thus providing a proxy measure for sea ice cover in the past. Analysis of sediment material collected with the help of Dr. A Rochon (UQAR) and his colleagues during the 2005 ArcticNet cruise revealed the presence of this biomarker across the entire Canadian Arctic Archipelago from the NOW region through to the Beaufort Sea. Notably, analysis of extracted sediments showed significant temporal and spatial variations in the concentration of the sea ice biomarker, indicating variations in sea ice cover in the past and between different locations. The aim of the current fieldwork was to obtain a series of sea ice cores encompassing various physical, temporal and spatial variations in order to investigate factors affecting biomarker concentration. These data would then be calibrated against satellite records of sea ice over the region.

A further aim of the current fieldwork was to collect sufficient amounts of representative species of the Arctic ecosystem in order to be able to perform analyses of their lipid contents and study the transfer of sea ice biomarkers across food chains. Planktonic specimens were collected using nets. Box core sediments were also obtained from stations relating to ice covered regions.

Sampling:
Box core sediments were collected from a range of locations in the Amundsen Gulf. Sampling consisted of both bulk homogenised surface sediments and high resolution (2 mm) sectioning over 20 cm cores.

Plankton net tows were collected at every opportunity throughout the cruise with samples from vertical tows (40 m water column ï 20 um) being stored separately and frozen (-20^{o}C) for later analysis in the UK to establish null results of biomarker content relating to open water conditions.

Sea ice cores were collected regularly until the ice melted in an attempt to capture the period of sea ice decay and the end of the spring bloom. Cores were sampled in triplicate to determine local variability in algal and biomarker production as well as from areas of low snow (~2 cm) and high snow (~30 cm) where possible to determine irradiance effects. Opportunistic cores were also sampled in interesting features such as pressure ridges, frozen cracks, lead edges, new ice (~10cm) and thin ice (~50 - 70cm). Cores were melted (bottom 10cm) and filtered (0.7 GF/F). Samples were frozen (-20^{o}C) and taken back to the UK for analysis. Dive samples were obtained from the onboard dive team. A scraping device previously manufactured on board to remove and collect the bottom 2~3 cm was used for bulk sampling. Slurp guns were also used to sample the under ice community. Samples were filtered (0.7 GF/F) and frozen (-20^{o}C).

Our analysis, briefly, consists of solvent extraction, open column chromatography and Gas Chromatography - Mass Spectrometry.

2.3.4. Inherent Optical Properties

PI: Pierre Larouche, Institut Maurice-Lamontagne (Pierre.Larouche@dfo-mpo.gc.ca)
Participant: Molly Palmer, Stanford University (mapalmer@stanford.edu)

Introduction:
The goal of this subproject of Team 3 was to investigate and explore the inherent optical properties of the Beaufort Sea and Amundsen Gulf region, in an effort to expand upon a database of measurements that began with the CASES project. Optical properties in this region show a strong terrestrial influence from the Mackenzie River, which severely biases the estimation of phytoplankton biomass obtained from remote sensing data. Satellite-based data is crucial to our ability to monitor and understand the complex biophysical processes in these remote coastal waters where other methods are often unavailable. Thus, the over-arching hope for these measurements is to develop specific methods and algorithms that will improve our ability to remotely sense biological properties in these high latitude, river-influenced areas, particularly in regards to the ocean color satellites SeaWiFS and MODIS.

Specific objectives for the 2007-08 CFL cruise are:

- The estimation of the ability of current bio-optical algorithms to measure chlorophyll-a concentration and species discrimination;
- The development of specific algorithms for a variety of ocean color sensors which will in turn provide a better understanding of the Beaufort Sea and the Baffin Sea physical and biological processes;
- The analysis of light absorption properties of arctic phytoplankton.

To reach these objectives, we will measure throughout the program the following parameters whenever possible:

(1) the transparency of the water with a Secchi disk;
(2) vertical profiles of inherent optical properties (light absorption and transmission, backscatter light, volume scattering function, particle size spectra, phytoplankton fluorescence, CDOM fluorescence, temperature and salinity using a custom built optical profiler system;
(3) the pigment composition of phytoplankton with the high performance liquid chromatography method (HPLC);
(4) the algal pigments light absorption;
(5) the total suspended matter and its partition into organic and inorganic matter;
(6) the chromophoric dissolved organic matter concentration (CDOM).

Methods:
Water samples were taken to measure inherent optical properties from June 7 to July 6. During leg 9A (June 7 - June 26), stations were predominantly in the ice; leg 9B was mainly open-water stations. The ice stations focused primarily on Darnley Bay and Franklin Bay, and included a unique transect from the ice pack in Franklin Bay out to the ice edge and then through to open water. As part of this transect, samples were collected remotely from the Horton River, which influences Franklin Bay, and these samples were analyzed as part of the regular dataset. The open-water stations were more variable both spatially and temporally, sometimes with multiple stations per day, and sometimes with several days between stations. The open water stations ranged from the southern tip of Banks Island, up to MðClure Straight, and out to the Mackenzie River, where samples were collected remotely and analyzed as well. See Table 3 for more information.

While at the ice stations, water was typically collected at 4 depths. Samples were taken at 2 and 5 m through a small hole cut into the ice (usually about 300-1000 m from the ship to avoid influence) using a pump and hose lowered into the hole. Ice thickness during this time ranged from a maximum of 180 cm in early June in Darnley Bay, decreasing to roughly 120 cm by the time we left Franklin Bay

directly ahead of the annual break-up. The ice during this time was relatively stable but covered with meltponds. Two other samples were taken using the rosette through the moon pool at 10 and 25 m.

During open-water stations, water was typically collected at 6 depths, which were optically determined where feasible. Thus, prior to each rosette, the Secchi disk was used in conjunction with UVA, UVB, PAR (all three with Eva Alou-Font) and PNF sensors to approximate optical depths of 50%, 10%, and 1%. The other depths collected from the rosette were the chlorophyll maximum, as indicated by the CTD; and 60 m depth. Finally, a surface water sample was taken either by dropping a bucket over the side of the boat, from the zodiac, or from the rosette (as a last-choice when no other alternatives were available).

Filtrations were performed for HPLC, a_{ph}, total suspended matter (TSM), and CDOM. For HPLC and algal pigments, water samples (up to 2.5 L) were filtered through 25 mm GF/F filters, flash-frozen, and stored in liquid nitrogen on the ship. CDOM samples were filtered using 0.2 ε m Anotop® syringe filters (Whatman) and collected into 60 ml acid-cleaned clear or amber glass bottles. The bottles were stored frozen (-20 ęC) in the dark on the ship. Total suspended matter was measured by filtering up to 2 L of water using pre-weighted 25 mm GF/F filters. The filters were stored on the ship at ï 80 ęC to arrest pigment degradation (Sosik 1999). The AC-9 was used for a few vertical profiles (contact Jens Ehn for details); more often, the PNF was used. Sample buckets and filtration towers were rinsed with 70% ethanol once a week; syringes for CDOM filtration were rinsed in a hydrochloric acid bath prior to use.

2.3.5. Rates of Carbon Fixation by Marine Phytoplankton

PI: Kevin Arrigo, Stanford University (arrigo@stanford.edu)
Participant: Molly Palmer, Stanford University (mapalmer@stanford.edu)

Introduction:
The goal of this subproject of Team 3 is to explore the relationship between photosynthesis and light in marine phytoplankton. Photosynthesis-irradiance curves provide a now-standard tool for understanding photosynthetic mechanisms and characterizing the response of microalgae to varying environmental conditions. Given the complex nature of the flaw-lead system and the sensitivity of this area to global change, these types of measurements are crucial for building a baseline database of knowledge for which to assess and predict future changes in the biological system.

Photosynthesis-irradiance curves rely on the precise measurement of radio-labeled carbon assimilation. The physiological response of phytoplankton to light saturation can be used to assess algal photoacclimation and maximum rates of carbon fixation (P_{max}) per unit chlorophyll *a* biomass. In this technique, a single, continuous function is used to describe the initial linear response (α, the photochemical reactions of photosynthesis) through to photoinhibition (β) (Platt et al. 1980; Jassby and Platt 1976).

Methods:
To determine rates of carbon fixation, we sampled phytoplankton assemblages from the ice, meltponds, and open water stations throughout Leg 9 of the CFL cruise. At most stations, only the chlorophyll max was sampled; one meltpond sample was also analyzed. Whenever possible, samples were pre-screened through 450 μm mesh.

Samples were incubated in a ñPhotosynthetronò at 19 light levels ranging from 6 μE/m^2/s to 900 μE/m^2/s, the majority of irradiances focused between 0-100 μE/m^2/s to characterize the initial linear response and P_{max} of the *P* vs. *E* curve (Figure 2). Approximately 235 mL sample was gently combined and stirred by hand with 12 mL 20 μCi $NaH^{14}CO3$ and added in 10 mL aliquots to 17 pre-chilled plastic scintillation vials (Wheaton) to obtain a final activity of 1 μCi in each sample. Light

levels were measured prior to and after the experimentation period using a Biospherical Instruments scalar PAR sensor. Samples were incubated for 2-hrs at -1.5°C. Immediately after incubation, samples were split into 5 mL subsamples and filtered through 5 μm polycarbonate filters and 25 μm GF/F (Whatman). The filters were then placed in plastic scintillation vials, and 100 μL 6N HCl and 1 mL milli-Q water was added to each vial. The vials were allowed to shake overnight in a fume hood. The following day, 100 μL of 6N NaOH was added to each vial, followed by 5 mL scintillation cocktail (Ecolume) was added. Each vial was shaken and left to sit for at least 3 hours and then counted in a scintillation counter.

In total, 15 P vs. E curves were completed from June 8 to July 4, 2008 (Table 5, Figure 3). Early curves focus on the ice algae community and follow the progression of a fairly large bloom in phytoplankton biomass (primarly dominated by diatoms such as *Thalassiosira* spp., as indicated by epifluorescence microscopy). Later in the sampling period, as the fast ice began to break-up, more open water stations were sampled, including near the south of Banks Island (Sachs Harbor), near the mouth of the Mackenzie River, and near Cape Bathurst.

2.3.6. Viability and Photoprotection

PI: Suzanne Roy (ISMER)
Participant: Eva Alou Font, ISMER (Rimouski), eva_alou @yahoo.com

Introduction:
Cell viability is a poorly known process in the ocean. Viruses and bacteria are implicated in cell mortality but cell death (e.g. apoptosis) can also be important. Recent work suggests than cell viability is strongly determined by the level of photo-protection in phytoplankton (Van del Poll et al., 2005).

With rapid global warming in polar environments ice reduction and melting should lead to increased irradiance in surface waters. Phytoplankton cells previously acclimated to lower light levels may then have insufficient photo-protection and consequently suffer significant mortality. Recent work linked cell survival with nutrient depletion in oligotrophic waters (Agusti et al., 2006).

Principal objective:
The objective of the project is to examine the flaw lead system and land fast ice in the Canadian Arctic during Spring time focusing on the following specific hypothesis:

1) To test whether photo-protection is a major determinant in changes in cell viability and this will contribute to difference between the composition of phytoplankton population from the flaw lead system and the land-fast regions.
2) To test whether cells from the more nutrient-limited regions show lower viability compared to nutrient-rich regions, when exposed to high surface irradiance.

Objectives:

1) Cell viability quantification.
2) Test cell photoprotection (Pigments, D1 protein cycle) vs. changes in viability.
3) Test nutrients vs changes in viability.
4) Test UV radiation vs changes in viability

To reach these objectives we measured the following parameters whenever possible:

1) Transparency of the water with a Secchi disk (to choose the right depths in the rosette).
2) Downwelling irradiance vertical profiles (UVb, UVa, PAR).
3) The pigment composition of phytoplankton with the high performance liquid chromatography method (HPLC).
4) Cell viability (Enzymatic technique and stain).
5) D1 protein.
6) Photosynthetic response (Xe-PAM).
7) Ratio of variable to maximum fluorescence Fv/Fm as a measure of the cell physiology activity (fluorometer).

Methods:

- Water samples were taken from June 6th until July 14th. Under the thin ice on the flaw lead system and in the water column in Open water stations. Samples under the ice were taken using a pump and a hose lowered through a small hole perforated in the thin ice with a handheld ice auger at surface level and 5 meters. Other samples under the ice where taken with the rosette, at 10 meters, 25 meters and depth of maximum chlorophyll when it was present until the mid leg change. In leg 9B all the stations where open water.
- In open water stations water samples where taken with the rosette according to the transparency of the water measured with the Secchi disk, normally at 50 % irradiance, 15% 1% and chlorophyll maximum when was present.
- Samples for HPLC technique were filtered through 25 mm GF/F filters with a maximum of 2 L each depth and then stored in liquid nitrogen on board.
- Samples for protein D1 were filtered through 25 mm GF/F filters with a maximum of 2 L each depth and then stored in liquid nitrogen on board.
- Cell viability was measured for each depth for posterior epifluorescence microscopy (microphytoplankton) and flow cytometry (Pico, nanophytoplankton) analysis.
- Vertical UV radiation profiles were done at each open water station.

Conclusions:

The CFL leg 9 operations where completed during 5th June to 13th July. We particularly thank the crewmembers and the rest of the members of team 3 who helped with operations.

2.3.7. The significance of viruses for polar marine ecosystem functioning

PI: Corina Brussaard
Participant: Claire Evans (Dept. Biological Oceanography , Royal Netherlands Institute for Sea Research, PO Box 59, NL-1790 AB Den Burg, Texel, The Netherlands)

email: claire.evans@nioz.nl
phone: +31 (0)222 369449 (direct)
or +31 (0)222 369300 (reception)
fax: +31 (0)222 319674

Background and Objectives:
Microbial communities (phytoplankton, bacteria, Achaea, heterotrophic protozoa and viruses) comprise the majority of the biomass in the oceans and drive nutrient and energy cycling, and are thereby important components of polar food webs. With the emergent awareness that viruses are major players influencing biodiversity and biogeochemical processes the need to elucidate their role in polar ecosystems has been underlined as, despite their likely importance, their quantitative significance has barely been studied. We aimed to complete a comprehensive study of the viruses and viral mediated processes of the Arctic marine habitats encountered during legs 8 and 9 of the Circumpolar Flaw Lead Study. Samples will be taken and experiments performed on organisms from both the water column and the sea ice. The objectives of this study are: 1) To examine the abundance and composition of viruses and their prokaryotes and eukaryotic hosts (In collaboration with Prof. C Lovejoy University of Laval, 2) To determine viral induced mortality on both prokaryotic and eukaryotic microbial hosts alongside host growth rates and mortality due to grazing. 3) To gather a data set allowing comparison of the viruses and viral mediated processes of the Southern and Northern Polar regions. 4) To collect sample from which viruses might be isolated and therefore available for laboratory experiments.

Work onboard:
A range of sampling was completed at four different station types which were; óLevel Oneô stations, óBacterialô water column stations, óAlgalô water column stations and óIceô stations. During the former RNA, DNA and pigments were sampled as part of a suite of other microbiologically-relevant measurements in collaboration with the other Microbiologist onboard (Mr D Nguyen University of Montreal). For more details see report of Mr D Nguyen. On bacterial water column stations measurements of abundance, diversity, grazing rate and viral-induced mortality were performed on the bacterial community at surface and/or chlorophyll maximum and bottom. On algal water column stations abundance, diversity, growth rate, viral lysis rate and grazing rate was determined on those algae present at the chlorophyll maximum. Finally at ice stations measurements were made to determine the abundance and diversity of the viruses and bacteria and the frequency of virus-infected bacteria. Details of the stations sampled are given in Table 7. At all experimental stations, samples were taken for viral diversity by concentrating 10 l volumes by 30 kDa ultrafiltration. These samples will be stored at -80 ºC until analysis by pulse field gel electrophoresis at the NIOZ. Samples for viral and bacterial abundance were fixed with glutaraldehyde, snap frozen and stored at -80 ºC for later analysis at NIOZ by flow cytomtery and SYBR Green.

Growth rates, viral lysis and grazing of the cyanobacteria, picoeukaryote, and nanoeukaryote communities present were determined by a dilution technique whereby whole water is combined with either 30 kDa filtered water (virus and grazer-free) or 0.4 um filtered water (grazer-free) in triplicate over a dilution series and incubated at *in situ* temperature and light conditions (environmental chamber). Fixed samples for algal enumeration were taken from all incubations at the start of the assay and after 24 h, allowing the calculation of growth rate. By plotting observed growth rate against the level of dilution the theoretical growth rate in the absence of mortality was calculated along with coefficients of grazing and viral induced mortality.

Rates of viral induced mortality of bacteria were determined by viral reduction assay. Briefly, the bacterial community was concentrated by tangential flow filtration and resuspended in viral free water generated by 30 kDa ultrafiltration. The production of viruses was followed by sampling for bacterial and viral abundance over a 12 h period (subsampling every 3 h). Rates of lysogenic infection of the bacteria were determined in identical experiments with the addition of Mitomycin C, inducing lytic production of any lysogenic phage. In addition, rates of viral infection of bacteria will be elucidated by determining the frequency of infected cells which will be performed at the NIOZ on samples preserved with glutaraldehyde. Grazing of bacteria was assessed by an exclusion assay whereby bacterial numbers within incubations filtered to remove grazers 0.8 um were compared with whole water incubations containing grazers. Samples for virus isolation were collected from the chlorophyll maximum and will be screened against potential hosts at the NIOZ.

Preliminary Results:
All measurements will be performed on preserved samples either at NIOZ for, flow cytometry of viruses, bacteria and phytoplankton, pulse field gel electrophoresis of the viral community, and transmission electron microscopy to determine levels of infected cells and at University of Laval for DNA, RNA and pigment samples.

2.4. Team 4

2.4.1. Pelagic Food web

Zooplankton, Fish Acoustic and Ecology

PI: Louis Fortier
Participants: Hélen Cloutier (U. Laval), Gérald Darnis (U. Laval), Samuel Lauzon (U. Laval), and Stéphane Thanassekos (U. Laval), and with the help of Alexis Burt (U. Manitoba)
Written by: Gérald Darnis and Stéphane Thanassekos and tables by Hélen Cloutier and Samuel Lauzon

Introduction
The fragmented, thin, and often absent ice cover in the flaw lead allows solar radiation to reach the surface layer of the ocean where it triggers photosynthesis by microscopic algae. Team 4, Pelagic and Benthic Food Web, investigates how and to what extent microalgae growing in the flaw lead are consumed by the zooplankton and reach the benthos and how physical processes affect the abundance, physiology and community structure of zooplanktonic organisms. Our simple hypothesis is that, relative to adjacent ice-covered regions, enhanced algal production in the flaw lead translates into biological hot spots where higher zooplankton and benthos production prevail. We also investigate how the Arctic cod, a central species in the Arctic food web, uses the flaw lead for feeding, overwintering, reproduction, and as a nursery ground for their young stages (http://www.ipy-cfl.ca/page1/page1.html).

General objectives
Our sampling program is derived from that of ArcticNet project 1.4 led by Dr. J.-É. Tremblay (U. Laval), ôMarine productivity and sustained exploitation of emerging fisheriesô, whose overarching goal is to assess the impact of sea-ice cover reduction and increasing sea temperatures on biological productivity, fisheries resources and marine mammal populations of the coastal Canadian Arctic. Since the beginning of the CFL field program last October, we focus on how physical processes moderate biogeochemical processes within the changing northern flaw lead ecosystem in the Amundsen Gulf - Banks Island area. The objectives of team 4 for leg 9 were to continue the work conducted during previous legs from the moon pool and to initiate the open water season by deploying zooplankton nets from the front deck (double (horizontal), quadruple (vertical) 1-m^2 nets, hydrobios and Rectangular Midwater Trawl) and from the zodiac (horizontal 1-m diameter ringnet) along the ice edge. We concentrated our sampling efforts on pelagic secondary producers as well as on larval, and juvenile Arctic cod. Our multidisciplinary ArcticNet-CFL team is strongly linked with Team 7 (Carbon Fluxes ï Tremblay) of the CFL program.

The primary objectives of our team during CFL leg 9 were:
1- To assess zooplankton / fish abundance and diversity by using various sampling devices.
2- To track zooplankton / fish biomass and distribution with the EK60 Echo sounder, and nets.

Our secondary field objectives were to collect and use zooplankton samples to:
1- investigate the cycling of contaminants by zooplankton and fish (G. Stern, U. Manitoba);
2- identify the sources and pathways of omega-3 in the Arctic marine food web (J. Michaud, E. Dewaily and L. Fortier, U. Laval). This project is linked to the CFL-URSUK program and ArcticNet theme 1.5, focusing on the importance of omega-3 fatty acids in the traditional diet of Inuit communities;
3- assess the biomass and respiration rates of the zooplankton community by the Electron Transfer System (ETS) activity at specific stations (G. Darnis and L. Fortier);
4- collect samples for stable isotope analysis of the food web structure and carbon fluxes; this is a joint project between Teams 4 and 7 of CFL (A. Forest, L. Fortier, J-E. Tremblay);

5- measure copepod *in-situ* egg production (EPR) and gonad maturation of *Calanus glacialis*, *C. hyperboreus* and *Metridia longa* (G. Darnis, L. Fortier);
6- validate the daily increment deposition on the otoliths of larval Arctic cod using a fluorescent marker (C. Bouchard, L. Fortier ï conducted by Helen Cloutier during LEG 9).
7- Increase the size of arctic cod larval dataset (length-at-age) in order to validate an individual-based model designed to calculate growth and survival of this species (S. Thanassekos, L. Fortier ï Measurements by Hélen Cloutier and Samuel Lauzon during LEG 9).

Sampling program

Leg 9 started at a landfast ice site in Darnley Bay. This period was devoted to moon pool sampling with at least one 1-m^2 vertical net cast per day and one Hydrobios every three days (Table 1 and 2). While the ship was static in the ice, the team used the hole prepared by the diving team to deploy the 1-m diameter ring net, in order to sample surface water that is typically inaccessible from the moon-pool (Table 3a). This net was also trawled twice during leg 9a and once during leg 9b, horizontally from the zodiac, as close as possible to the marginal ice zone with the objective to catch arctic cod larvae (Table 3b).

Every three-four days, the ship made excursions out of the ice, in open water and open deck activities started on June 10th with a vertical monster net tow (Table 4) and an oblique double Tucker net tow (Table 5). As the Rectangular Midwater Trawl was deployed for the first time after winter during CFL, its preparation delayed its deployment to the 16th of June (Table 6).

Real open water operations began on June 23rd at Full Station 1216, after the installation of the Hydrobios on the front deck. We also had the opportunity to sample for the first time in MôClure strait on July 6th at station 2010.

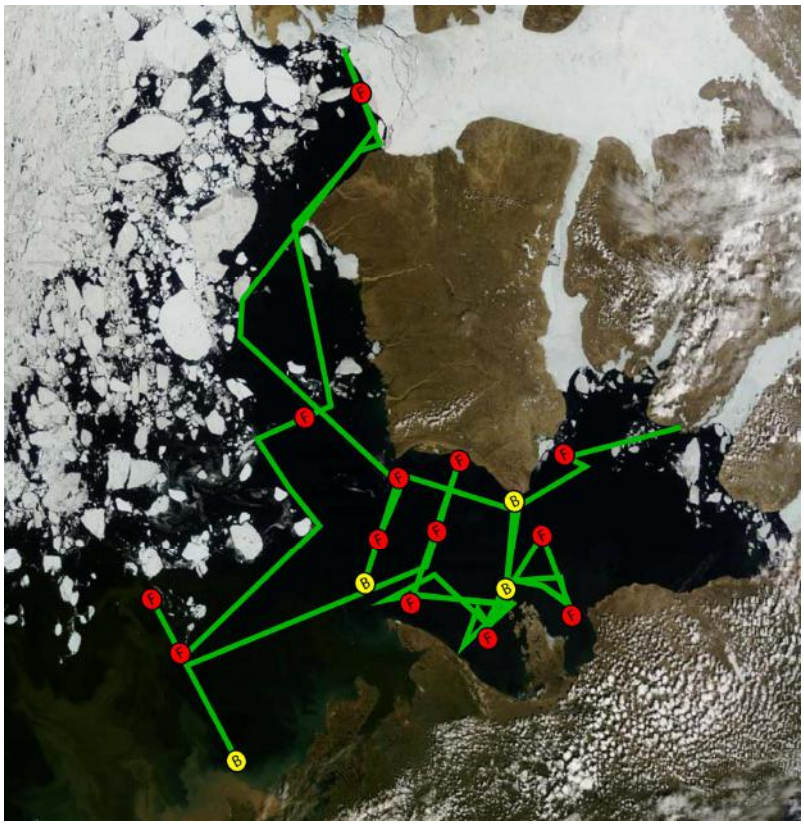

Figure 1. Location of stations (F: Full, B: Basic) visited during CFL leg 9.

Description of the sampling devices used during leg 9

a) **Rosette**. Samples to investigate the vertical distribution of the micro-zooplankton were collected from the rosette twice during leg 9.

b) **1-m² square net**. A 1-m^2 square metal frame rigged with a 200 µm mesh plankton net, an external 10 cm diameter 50 µm net and equipped with a TSK flow meter. This instrument is used to obtain integrated water column samples. Downward and upward winch speeds are 40 and 30 m/min respectively. Quantitative samples from both nets for taxonomy and abundance estimates are preserved in formaldehyde. Qualitative samples (i.e. "live tows") are also collected to obtain animals for contaminants, lipids, EPR and ETS studies.

c) **Hydrobios** (Fig. 2a). Multi-depth plankton profiler equipped with nine 200 µm-mesh nets (opening 0.5 m^2) for depth specific sampling of the water column. The Hydrobios is also equipped with a CTD to record water column properties while collecting biological samples. Downward and upward winch speeds are 40 and 30 m/min respectively. For most casts, the net collection was preserved in formaldehyde for taxonomic analysis. However, the content of each net from some deployments was divided 50% for taxonomy (4% buffered formaldehyde), 25% for biomass estimates and 25% for ETS analysis.

d) **1-m diameter ring net** (Fig. 2b). A 1 m diameter metal ring equipped with a 200 µm mesh net, an external 10 cm diameter 50 µm net, and central G.O. flow. This net was deployed from a hole in the ice at proximity of the ship but at a site not influenced by its presence during LEG 9A. The net was lowered and pulled up manually. The ring net was also trawled horizontally along the ice edge, as close as possible, with a zodiac at a 2 knot speed.

e) **Monster net** (Fig. 2c). Four 1-m^2 metal frames attached together, one rigged with a 1-m^2 500 µm mesh net and a G.O. flow meter for contaminant sampling, one with a 1-m^2 200 µm mesh net and a TSK flow meter for abundance measurements, two with a 1-m^2 200 µm mesh net without a flow meter for "live" sampling, and an external 10 cm diameter 50 µm net. The gear is deployed vertically from 10 meters off the bottom to the surface. Downward and upward winch speeds are 40 and 30 m/min respectively.

f) **Tucker net** (Fig. 2d). Two 1-m^2 metal frames attached together each rigged with a 1-m^2 500 µm mesh net, an external 10 cm diameter 50 µm net and equipped with a TSK flow meter. The gear is deployed obliquely to 90 meters or less (depth determined by cable length and angle). Downward and upward winch speeds are 30 and 20 m/min respectively.

g) **Rectangular Midwater Trawl (RMT,** Fig. 2e**).** Trawl with an opening of 9 m^2 fitted with a 1600 µm mesh-net. When towed, ship speed was typically 2-3 knots; and winch speed down was 30 m/min and around 20 m/min on the way up. This net, only deployed at full stations, was used to catch larval and juvenile fish. Collected zooplankton was equally divided for taxonomic and contaminant studies.

h) **64 µm ring net** (Fig. 2f)**.** This 50-cm diameter aperture net was essentially used to collect live organisms as food for the cod larvae that were incubated for the otolith marking experiment (Helen Cloutier). It was deployed from 30m to surface by hand from either the moonpool or the front deck in open water. It was also used on ice from the dive hole (hole prepared by the diving team during LEG 9A).

Sampling events during leg 9

Overall, 131 sampling events occurred from which 72 samples were preserved for taxonomy. Samples from the "dive tows", were used for further analyses and laboratory experiments as described below. Samples for lipid and stable isotopes analyses were placed in cryovials and stored at -80°C. Other samples were preserved as a *bulk* at -80°C for later gut fluorescence measurements. All these samples will be sorted and analysed at Laval University. Samples for contaminants were sorted and preserved by Alexis Burt (Dr. Stern's team, U. Manitoba).

The first three weeks of leg 9 were spent in the decaying landfast ice in either Darnley or Franklin Bay. The fragility of the ice prevented the deployment of motorised vehicles that would have permitted to pull the nets from ice holes. As a consequence the zooplankton team work on the ice was limited to the deployment of shallow ringnets trawled by hand. Furthermore, when checked the EK 60 recordings did not show any significant presence of fish and fish cage deployment from the moonpool

was therefore cancelled. The few spotted echosounder targets actually proved to be amphipods aggregations as validated by the nets and the diversô observations under the ice. No aggregations were seen at the bottom of the water column. The two landfast ice sites displayed different ecosystem structures. The water column in Darnley bay was characterised by huge sticky aggregates of algae that clogged the nets and suffocated the zooplankton in the samples. Very few Arctic cod larvae were collected at this site. The two fast ice sites were too shallow to give interesting estimates of zooplankton vertical distribution with the Hydrobios. Therefore, the only interesting vertical profiles were limited to the three excursions in deeper waters that were made once a week during leg 9A. Our first significant collection of cod larvae occurred on the 14 June while transiting to Franklin Bay (Table 7). A total number of 1351 larvae were caught during LEG 9, 610 where measured (and around half of these were frozen to measure their fresh un-preserved weight back at university), and 741 were preserved in ethanol. 564 larvae were captured with the double Tucker, 228 with the Monster net and 519 with the RMT. The 200 khz transducer could not be deployed for most of leg 9A because its cable broke and rust built up in the tube to the bottom of the hull before the cable could be changed. As a consequence, data for the 200 khz wavelength of the EK60 could not be recorded for this period.

Leg 9B was mostly devoted to open water sampling. Thirteen Full stations and 4 Basic stations were visited. At a typical full station, the Hydrobios, Monster, Oblique tucker, RMT and 64 µm ringnet were deployed whereas only the Monster, 64 µm ringnet and the Oblique tucker were used at a Basic station. Time between stations was short and the variety of gears, experiments and processing of fish larvae made this sampling period intensive. Thanks to the good weather conditions and the professionalism of crew, team members and chief scientist, all the deployments were made easy and successful. We were able to deploy the Hydrobios below 1000 m (Station 421) for the second time since it is part of the scientific equipment of the Amundsen.

Laboratory analyses

1) **Egg production rate experiments (EPR)**
   Copepod *in-situ* egg production rate (EPR) were monitored by incubating the females of two species (*Calanus glacialis* and *Metridia longa*) at 0°C, a temperature similar to that they experience in their environment. The results from the experiments conducted during leg 8 showed that the egg production season is over for *C. hyperboreus* but still underway for *C. glacialis* and *Metridia longa* and continued on leg 9. Often, poor abundance of females *C. glacialis* and the high concentration of algae in the zooplankton samples limited our capacity to sort enough organisms for the EPR experiments. Thus the number of experiments is lower than for the previous legs for this species.
2) **Biomass and Transfer System (ETS) activity**
   Samples were sorted for biomass and ETS activity assays at 11 Hydrobios stations (Table 2). At these stations, each Hydrobios net was subdivided: 50% for taxonomy (i.e. preserved in formol), 25% for population biomass estimates and 25% for ETS activity measurements. For biomass estimates, the sub-sample (i.e. 25% of total sample) was fractionated with sieves in > 1000 µm and < 1000 µm size classes; these fractions were preserved at -0ęC. Sub-samples for zooplankton population ETS activity assays (i.e. 25% of the total sample) were also sieved through the same two size fractions. As no Sanyo incubator was available for the ETS experiments, samples were incubated in a Pyrex plate filled with water and heated to 40ęC on a hot plate. Temperature of this ôhot tubô proved to remain constant during the required incubation time. ETS experiments were also performed on individual copepods (females and copepodite stage 5) of *Calanus glacialis*, *C. hyperboreus* and *Metridia longa*.
3) **Respiration experiments**
   To derive respiration from the activity of the Electron Transfer System (ETS), a ratio of respiration on ETS activity is required. Thus eight incubations were carried out to measure oxygen consumption of zooplankton assemblages and selected copepods species in sealed chambers.

Acoustic monitoring

The Simrad EK-60 Echosounder of the Amundsen allows our group to continuously monitor the spatial and vertical distribution of zooplankton and fish, the later mostly represented by Arctic cod (*Boreogadus saida*). The hull-mounted transducers are in operation 24h a day and will provide an extensive mapping of where the fishes are within the region of interest over a yearly cycle.

General Recommendations:

For an unknown reason, the lab incubator had a warming episode (up to 16°C) despite regular defrosts and no door opening (that happened early in the morning before anybody had come to the lab for that day). Continual monitoring of the incubator and defrosting every day, especially if the door is opened often, should be accomplished.

Acknowledgements. We thank the officers and the crew of Amundsen team B and Sylvain Blondeau for their continuous effort and essential help; thank you for being able to repair or built anything we need! Special thanks to Alexis Burt for the precious help and encouragement given on the foredeck and in the lab, to Dan Nguyen that provided us with litres and litres of filtered sea water, and finally to CJ Mundy for being a wonderful chief scientist.

2.4.2. Benthic Food web

PIs: *Team 4* (Food webs): Philippe Archambault (University of Quebec at Rimouski, Canada) and Dieter Piepenburg, (University of Kiel, Germany); *Team 7* (Carbon and Nutrient Fluxes): Paul Renaud, (Akvaplan-niva, Norway), and Tobias Tamelander (University of Tromsø, Norway)

Participants: Heike Link (9A and 9B), University of Quebec at Rimouski, Mylène Bourque (9B), University of Quebec at Rimouski

Background

On leg 9, the benthic work was continued according to the activities of the team from legs 3, 7, and 8 as part of Team 4 (Food webs) and Team 7 (Carbon and nutrient fluxes). This included deployments of the box corer and grab for retrieving seafloor sediments and the Agassiz trawl for sampling epibenthic communities.

The research is based on the hypothesis that sea ice dynamics control the trophic structure and vertical fluxes and, hence, the 1) strength of pelagic-benthic coupling as well as 2) abundance, composition, diversity, and carbon demand of the benthic communities, which should therefore differ between the flaw lead polynya and the (ice-covered) rest of the shelf. This means, vice versa, that a comparative quantitative inventory of the benthic community structure and metabolism under the flaw lead and the land-fast ice will allow for assessing the effect of the ice regime on pelagic-benthic coupling. Furthermore, the work will contribute to the overarching objective to describe and compare the biodiversity and secondary productivity of benthic communities in areas of enhanced and reduced (ñhot spotsò and ñcold spotsò) productivity and diversity in the Canadian Arctic.

The spatial distribution and seasonal dynamics of the benthic community structure and metabolism is planned to be characterized by repeated sampling over a pre-defined sampling grid throughout a large part of the CFL study period. Samples have been collected during leg 3 in October/November 2007, and since leg 7, starting in March 2008. The field work will be continued during the following leg 10, thus covering a period of time from March to August 2008 and forming a time series of the seasonal patterns of benthic community structure and metabolism. As the sampling is intended to embrace a broad range of benthic size groups (to describe the benthos as comprehensive as possible), a variety of sampling gear will be employed (box corer, grab, Agassiz trawl, epibenthic sled, ROV).

The **box corer** is deployed to quantitatively sample macrobenthic infauna (team 4) and obtain sediment cores which are used to determine sediment properties and the carbon utilization and nutrient recycling by the benthic community (team 7). The second objective contributes to the overall team 7 goal to comparatively quantify major fluxes and pathways of carbon and nutrients over the annual cycle in the flaw lead and fast-ice regions. Within this context, the contribution of the benthos in the overall marine carbon flux will be estimated by determining the carbon demand of the seabed fauna. This, in turn, will be assessed by measuring the sediment oxygen uptake, i.e. by incubating sediment cores and following the decrease of dissolved oxygen in the ambient overlying water with time. These measurements provide a bulk parameter, commonly termed the 'sediment oxygen demand' (SOD), integrating total aerobic respiration of the community of benthic organisms contained in the core.
At the same time, changes in nutrient concentration for ammonia, nitrate, nitrite, silicate and phosphate in the ambient water are measured, to gain first knowledge on the role of benthic activity for the nutrient cycles in Arctic waters.

The **Agassiz trawl** is used to survey epibenthic diversity and abundance of species. Where possible, this data should be compared to visual surveys conducted by the ROV.

The **ROV** work is aimed on an analysis of the epibenthic macro- and megafauna, in order to complement concomitant survey work, using the box corer, targeting other smaller size groups of the benthic assemblages (e.g., endobenthic macrofauna).

Material and Methods

The box corer was deployed at 14 stations (Table 1) between MðClure Strait and the Amundsen Gulf south-east of Banks Island at water depths ranging from 45 to 563 m between 10 June and 13 July 2008.

From 12 box corers, seafloor sediments were collected with a total of five replicate sub-cores (with a diameter of 11.5 cm, i.e., an area of 0.1 m^2 each, down to sediment depths of 15 to 20 cm) for subsequent on-board SOD incubations. Three sediment cores with a 10.0 cm diameter, 15 cm depth, were collected for onboard bioturbation experiments. In addition, three sub-cores for chlorophyll *a* (diameter of 5 cm each) and three sub-cores for CN analyses (2.54 cm diameter each) were taken from each box core. Sub-cores for chlorophyll *a* were sliced in 1 cm sections to 10 cm depth. For CN, the top 2 cm were collected. These samples were frozen and transported off the ship for analyses in the home lab. (Fig. 1)

From two box corers and four grabs, sediments of a surface area of 0.125 m^2, varying 10-15 cm in depth were collected and passed through a 500 mesh sieve and preserved in a 10% buffered seawater formalin solution for further identification in the laboratory.

Incubations of sediment sub-cores were performed in a dark and temperature controlled room (ca. 3 °C) in the zooplankton container (front deck, port side). The decrease in oxygen concentrations in the water overlying the sediment (bottom water collected from rosette water samples obtained at the same station) in the incubation cores was measured periodically (6-8 h intervals) over 1-3 days to assess SOD.

Nutrient samples from the ambient water were taken at the start of incubations (ca. 100 % oxygen in the water), at midway (ca. 90 % oxygen), and at the end of incubations (ca. 80 % oxygen). Except ammonia, nutrient concentration was analysed by Jean-Eric Tremblayôs Team onboard.

Fig. 1: Boxcore with SOD/Nutrient cores (grey), bioturbation cores (white), Chlorophyll a cores (orange), CN cores (syringes), and a biomarker core (black).

Three incubation cores containing water only acted as controls. At the end of the incubations (after 15 to 20% of the oxygen has been consumed), the sediment in the cores was sieved on a 0.5 mm mesh sieve, and the sieve residue, including fauna, was preserved in a 10% buffered seawater-formalin solution for later analyses of species composition, abundance and biomass.
For bioturbation experiments, luminophores were added to the sediment surface and then cores were held with oxygen saturated overlying water for 10 days in the incubation room. At the end, cores were sliced in 0.5 cm slices for the first 3 cm, and the 1 cm slices until the bottom of the core. Samples were frozen and transported to the home lab for further analyses.

Table 1: Benthic sampling stations during leg 9, with number of cores collected for Sediment Oxygen Demand (SOD), bioturbation experiments, Chlorophyll a (Chl), CN, number of samples for diversity, and type of samples for other groups (Biomarkers, Contaminants).

The **Agassiz trawl** was successfully deployed at a total of 10 stations between Mc Lure Strait and the Amundsen Gulf south-east of Banks Island at water depths ranging from 45 m to 420 m. Species were counted or estimated in abundance and identified to the lowest possible taxonomic level. Some specimens were preserved for further identification in the home lab.
The **ROV** was not deployed during leg 9.

Preliminary Results
Benthic communities showed a generally higher SOD than in leg 7 and 8. During this leg, we revisited and sampled the stations D34, 9002, and 405B for SOD. At all three stations, oxygen consumption had strongly increased compared to the results at these stations from leg 7 or 8. These results reflect the increase in benthic metabolic activity after the algal bloom and the associated sinking of organic material to the seafloor. However, data still need to be analysed more thoroughly, taking temperature and benthic biomass changes into account.
Diversity and abundance of epibenthic communities sampled by the Agassiz trawl varied between sites. At 2 rocky sites, crinoids (*Heliometra sp.*) were dominating, whereas several species of ophiurids predominated on homogenous soft-bottom sediments. At the rocky but deep (420 m) station 2010, *Ophiura sarsi* was the most abundant species.
Beside other polychaetes, molluscs, pycnogonids, sipunculids, decapods, amphipods, holothuroids, asteroids, and bryozoans, *Ctenodiscus crispatus* (Asteroidea), *Mesidothea sp.* (Isopoda) and *Astarte sp.* (Bivalvia) were found at several sites. Closer identification and analyses of assemblage composition will be conducted after the end of the field work.

2.5.1. Surface Meteorology and Flux Project

Introduction
The surface meteorology and flux program (CFL Team 6) is designed to record basic meteorological conditions and to study exchanges of momentum, heat and mass across the atmosphere-sea ice-ocean interface. The main value of this program to the overarching objectives of Team 6 is the direct measurement of CO_2 fluxes.

Turbulent fluxes of CO_2 are measured by the eddy covariance technique, which is dependent only on atmospheric measurements. Although measurement of these fluxes is extremely useful information, it is essentially meaningless without an understanding of the processes (physical, biological and chemical) that drive gas exchange. In an open-ocean situation this context is largely provided by measurement of sea-surface pCO_2, but the situation becomes much more complex when a sea ice cover is included in the equation.

This section of the CFL Team 6 cruise report reviews the atmospheric and sea surface pCO_2 measurements that were made during Leg 9. Other sections of the annual report will deal with the sea ice measurements that were made in support of the CO_2 flux measurements.

Amundsen Micrometeorology and Eddy Covariance Flux Tower

Methods
The micrometeorological tower located on the front deck of the Amundsen (Figure 1) provided continuous monitoring of meteorological variables and eddy covariance parameters. The tower consists of slow response sensors that record bulk meteorological conditions (air temperature, humidity, wind speed/direction, surface temperature) and fast response sensors that record the eddy

covariance parameters (CO_2/H_2O concentration, 3D wind velocity, 3D ship motion, air temperature) (Table 1). In addition, radiation sensors (Figure 1, Table 1) were installed on the roof of the wheelhouse to provide information on incoming longwave, shortwave and photosynethetically active radiation. All data was logged to Campbell Scientific dataloggers; a model CR5000 logger was used for the eddy covariance data, a CR1000 logger for the slow response met data, and a CR23X for the radiation data. All loggers were synchronized to UTC time using the shipôs GPS system as a reference.

The eddy covariance system on the tower makes use of two separate gas analyzers and a single 3D sonic anemometer. The dual gas analyzers system allows us to make use of both closed path and open path eddy covariance systems. The open path gas analyzer has the benefit of making measurements concurrently with the sonic anemometer, but the closed path gas analyzer is not as easily disturbed by adverse weather conditions.

In order to make sure that the two systems are comparable, careful calibrations were performed on both instruments. The closed path system is based on a LI-7000 gas analyzer which employs two optical cells, one of which was used to monitor the drift of the instrument by constantly passing a stream of ultra-high purity N_2. In addition, the sample cell of the instrument was calibrated daily using the ultra-high purity N_2 to zero the CO_2 and H_2O measurements, and a reference gas of known CO_2 to span the instrument. Occasionally, a span calibration of the H_2O sensor was performed using a dew point generator (model LI-610).

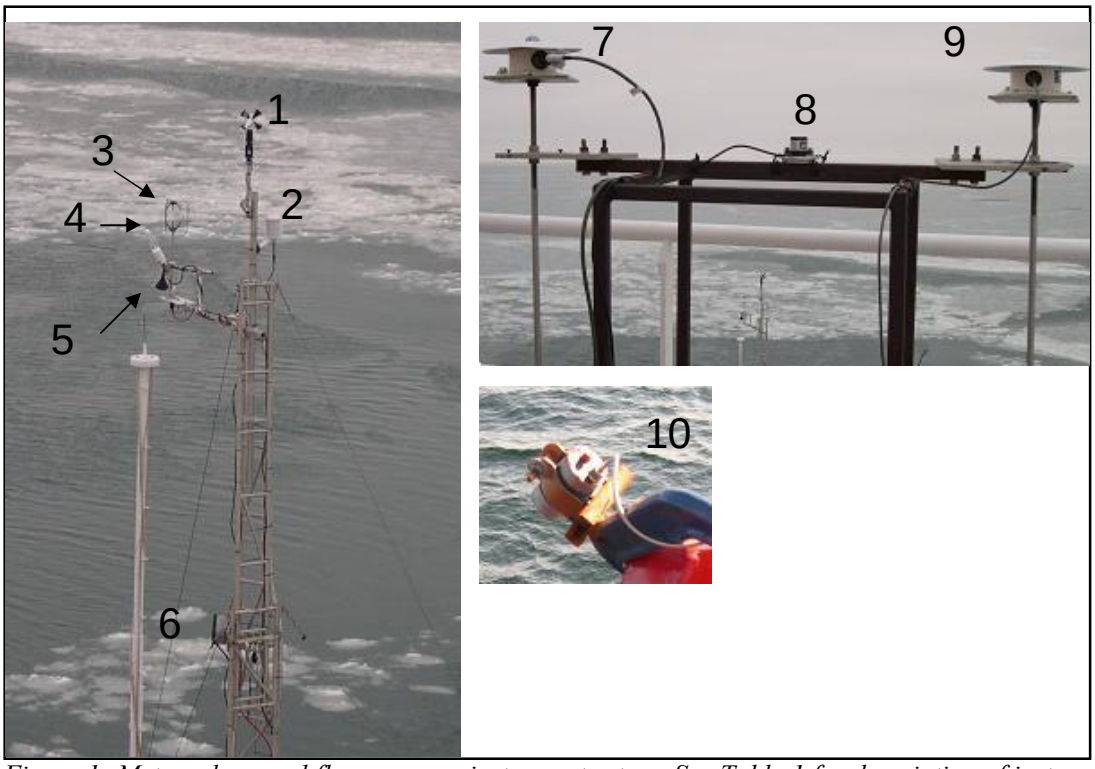

Figure 1: Meteorology and flux program instrument setup. See Table 1 for description of instruments based on the numbers. Note that on Nov. 18 the Motion Pak (6) was moved to the rear face of the tower to facilitate easier motion correction.

Notes

The meteorological tower ran consistently for the duration of the leg (June 5 ï July 16) with the exception of brief periods when the tower was taken down for maintenance. However, for significant periods of time during the leg certain sensors were inoperable due to atmospheric conditions. The most common problem encountered during this leg was riming due to the cold, moist conditions. The extent of data lost due to atmospheric conditions cannot be estimated at this time, and will only be known once post processing is complete.

Ice-Based Micrometeorology and Eddy Covariance Flux Tower

Methods

A portable 2m tower was deployed on the ice in close proximity to the ship to measure meteorological data in conjunction with the data collected on the ship-based tower (Figure 2). The tower consisted of slow response meteorological instruments (wind speed/direction, air temperature, relative humidity, surface temperature, upwelling and downwelling shortwave and longwave radiation) and fast response flux instruments (3 dimensional wind velocity, sonic temperature, CO_2/H_2O fluctuations from open and closed path sensors). All data was logged using a Campbell Scientific CR3000 datalogger that was synchronized to UTC time using the shipôs GPS system.

Figure 2: The portable ice meteorology/flux station. For this deployment, the closed path sensor and radiation sensors were not included. They were included in later deployments (see Table 2).

Deployments

Table 2: Site and deployment information for ice-based meteorology tower

Deployment Date (UTC)	Removal Date (UTC)	Notes
Jun. 11, 20:50	Jun. 14, 03:35	No radiation sensors. Closed path eddy covariance system installed June 12, 15:40.
Jun. 18, 17:50	Jun. 19, 12:00	Tower located ~150m southeast of ship (shipôs heading 90º); radiation sensors located ~8m west of main tower; sonic anemometer pointing to east

On-track pCO2 System

Methods

A custom-built pCO_2 system was utilized on this leg to measure dissolved CO_2 at the sea surface in near real time. The system (Figure 3) is located in the engine room of the Amundsen, and draws sample water from the shipôs clean water intake. The water is passed into a sealed container through a shower head, maintaining a constant headspace. This set up allows the air in the headspace to come into equilibrium with the CO_2 concentration of the seawater, and the air is then cycled from the container into a LI-7000 gas analyzer in a closed loop. Thermocouples are used to measure water temperature immediately before entering the equilibration chamber, and to measure the temperature of the air in the chamber. All data is logged to a Campbell Scientific CR1000 datalogger.

The LI-7000 gas analyzer was calibrated daily using ultra-high purity N_2 as a zero gas, and a gas with known CO_2 concentration as a span gas. Spanning of the H_2O sensor was not necessary because a desiccant column removes H_2O from the air stream before passing into the sample cell. As with the closed path system, a stream of N_2 is constantly cycled through the reference cell of the LI-7000 to monitor and correct for drift of the instrument.

Figure 3: The on-track pCO_2 system located in the engine room of the Amundsen. The equilibration chamber is the clear cylinder (left bottom) and the gas analyzer is the box with the digital display.

Notes
The on-track pCO_2 system was active for the duration of the leg, with some minor interruptions for maintenance. Major interruptions in data collection were experienced when the ship was breaking ice, which either reduced the flow of water into the equilibration tank, or completely blocked it. In the case of blocked flow, the data is lost, but tests will have to be conducted to determine if data obtained with low water flow is useful.

During this leg, we expanded testing of the accuracy of the system by drawing samples from the water inlet line for DIC analysis. This was conducted 4 times throughout the cruise. Preliminary results suggest that the pCO_2 values calculated from the DIC samples match very well with the equilibrator values.

2.5.2. Sea Ice Biogeochemistry

In-Situ measurements and Ice Core Collection

In order to get a set of biogeochemical variables that will help us understand the dynamics of processes happening in sea ice and seawater, we collected ice cores for further analysis in both Winnipeg, Brussels and Liege labs. Basically, we took between 10 and 12 cores at each station. A major concern throughout the whole sampling procedure has been to prevent contamination of trace metal samples, especially iron. We followed the trace metal clean procedures proposed by Lannuzel et al. (2007). Nitrile gloves were used for handling the iron dedicated samples, and items used for sample collection and storage were acid-cleaned and sealed in plastic bags. The electropolished stainless steel core barrel (Lichtert Industries, Brussels, Belgium) has been specially designed and tested to be non-contaminant for iron. Seawater was pumped up with a portable peristaltic pump (Cole-Parmer, Masterflex E/P). Finally, the sea ice cores dedicated to iron determination were immediately packed in cleaned plastic bags and stored at minus 25 degrees Celsius.

Additionally, we measured a couple of standard variables in the field (e.g., freeboard, snow thickness, snow temperature). A complete list of the variables for the leg 9 is presented in Table 3.

Brine and Seawater Samples

Sampling of brine from the sea ice was conducted by drilling shallow sackholes (ranging from 20 cm down to almost full ice thickness) through the surface of the ice sheet. The brine from adjacent brine channel and pockets was allowed to seep into the sackhole for 15-120 min (depending on ice temperature), with the hole covered with a plastic lid (Gleitz et al., 1995), reportedly the best current method to sample brines for chemical studies (Papadimitriou et al., 2004). Brine and sea water were pumped from the hole using a peristaltic pump (Masterflex® - Environmental Sampler).

Samples for alkalinity (TA), dissolved inorganic carbon (DIC), chlorophyll (chl), pCO_2, temperature, salinity, O^{18}, and DMS were taken.

Analysis for DIC and TA was performed using the VINDTA 3C (Versatile Instrument for the Determination of Titration Alkalinity) developed by Marianda (see section 4).

Chlorophyll, temperature and salinity were also measured immediately onboard (AO).

The samples for O^{18} and DMS will be sent back to Brussels and analyzed.

The pCO2 was measured directly on the field using the Sea Ice Equilibrator System (SIES). This device allows measurement of pCO_2 by utilizing a membrane contractor equilibrator (Membrana® Liqui-cell) coupled to an infrared gas analyzer (IRGA, Li-Cor® 6262). All instrumentation of the SIES unit were enclosed in an insulated box that contained a 12V power source and was warmed to keep the inside temperature just above 0°C. Seawater flow through the equilibrator at a rate of 1 L min^{-1} and a closed air loop ensures circulation through the equilibrator and the IRGA at a rate of 3 L min^{-1}. Temperatures were measured in situ simultaneously in the brine sackhole and at the outlet of the SIES unit. A temperature correction of the pCO_2 was applied assuming that the relation from Copin-Montégut (1988) is valid at low temperatures and high salinities. The IRGA was calibrated using CO_2-in-air standards with mixing rations of 0 ppm and 369.4 ppm of CO_2 supplied by Air Liquide Belgium® shortly after returning to the ship (while the IRGA was still cold). Stable field pCO_2 readings could take considerable time to obtain (up to 1 hour from turning on the flow of gas) especially when pCO_2 values were low in the brine.

Gas chamber measurements

A chamber coupled to the SIES was used to measure air-ice CO_2 fluxes. The accumulation chamber (West system®) is a metal cylinder closed at the top (internal diameter 20 cm; internal height 9.7 cm). A rubber seal surrounded by a serrated-edge iron ring ensured an air-tight connection between the base of the chamber and the ice. For measurement over snow, an iron tube was mounted at the base of the chamber to enclose the sampled snow down to the ice and to prevent lateral advection of air through the snow. The chamber was connected in a closed loop between the air pump (3 L min^{-1}) and the IRGA of the SIES. The measurement of pCO_2 in the chamber was recorded every 30 sec for at least 10 min. The flux was computed from the slope of the linear regression of pCO_2 against time (r^2 Ó~ 0.99) according to Frankignoulle (1988). The uncertainty of the flux computation due to the standard error on the regression slope is on average ±3%. CO_2 fluxes values correspond to the average of three measurements. The idea is to look at the changes in the pCO_2 between the beginning and the end of the

gas chamber deployment. Any increase in this pCO_2 can then be understood as a positive flux from the ice ï any decrease as a negative flux.

We did several gas chamber measurements during the main coring stations but also during small punctual stations. In order to investigate the influence of the ice properties on the fluxes, we put the chamber on different ice types and thicknesses.

Ice Cores

All the ice cores are stored in a freezer container onboard.

In the field temperature of the ice is taken directly after the extraction of an ice core. After, on the same ice core we cut it each 5 cm to measure salinity but also chlorophyll, and to take samples for O^{18}. Towards the end of the leg, when the sea ice was warm and significant brine drainage occurred after sample removal from the core hole, ice cores were cut into 5 cm segments and placed in buckets immediately in the field.

Onboard, the ice core was melted in a cold room at +4°C for the study of minerals of $CaCO_3$ and ikaite. The melt water was filtrated on a GF/F and the filter was stored in the freezer container for further analysis back in Belgium.

DMS/P/O contents in sea ice, brine and water

Material and methods
The purpose of the DMS/P/O project is to measure the DMS/P/O contents in sea ice, brine and water during leg 8 and 9a in order to determine the dynamics of those compounds in the ice and between the mediums. Another point of interest is to follow the evolution of those concentrations over time and to look at the potential interactions and influences of the biogeochemistry of sea ice on DMS/P/O. The work is undertaken in collaboration with Dr. Maurice Levasseur (U.Laval).

Basically, we took ice cores, brine and water samples at different locations representing different ice types and thicknesses. Ice samples were taken using a electropolished stainless steel corer and liquid samples were put into air tight vials with the help of a peristaltic pump or syringes. The vials were stored in the dark at 4 ºC before analysis to minimize biological activity.

Liquid samples (DMSP and water/brines samples) were analyzed with the Purge and Trap system and the GC. This system uses helium as a carrier gas to remove all the DMS from the container and to accumulate it into a teflon loop immerged into liquid nitrogen in order to capture the DMS. When all the DMS is trapped the loop is put into hot water and all the gas is released into a gas chromatography system (GC Varian with a six way valve, a column specific for sulfur and a PFPD detector).

During leg 9a, all the liquid samples from brine and sea water were analyzed on the ship.

2.5.3. Laser Wave System (LAWAS) Project

The University of Miami LAWAS consists of 4 Riegl LD90-3 laser altimeters mounted in a square array of 0.3m diameter. LAWAS is mounted on a boom near the bow on the port side (see Fig. 4). A Systron Donner MotionPak is mounted at the center of the array to measure all six components of motion of the laser array.

Fig. 4 Photographs showing LAWAS position near bow of Amundsen.

The LAWAS system is designed to measure time series of wave slope in two directions, from which rms slope of the sea surface can be calculated. Of particular interest are measurements coincident with Quiksat overpasses. Typically eight overpasses occur each day, between 01 ï 13 UTC. The project objective is to relate CO2 gas transfer to Quikscat derived backscatter measurements. LAWAS deployments took place on June 27th, 28th,30th , July 2nd, 6th ,7th , 8th, 9th , 10th , and 12th during several satellite passages each time. Data was obtained during stations, but also at full ship speed and at 7 knots (maximum ship speed before bow-generated wake appears).

2.6. Team 7

The Arctic climate displays high inter-annual variability and decadal oscillations that modulate growth conditions for marine primary producers. Much deeper perturbations recently became evident in conjunction with globally rising CO_2 levels and temperatures (ACIA 2004; Comiso 2003). The thickness and extent of Arctic sea-ice decrease rapidly (Johannessen et al. 1999; Rothrock et al. 1999) and the ice-free season is extending both in the Arctic (Laxon et al. 2003) and subarctic (Stabeno & Overland 2001). Models predict further reductions in ice cover (ACIA 2004). These changes entail a greater penetration of light into surface waters, which is expected to bolster phytoplankton production (Rysgaard et al. 1999), food web productivity and CO_2 drawdown by the ocean. At present, phytoplankton production varies by two orders of magnitude across the Canadian Arctic, but the forcing mechanisms are poorly understood and quantified. In the Canadian Archipelago, the productivity of phytoplankton is likely to be limited by light or the supply of allochtonous nitrogen, depending on ice conditions. The supply of allochtonous nitrogen is influenced by climate-driven processes, mainly the large-scale circulation, river discharge, upwelling and regional mixing processes. Over most of the western Arctic, and especially the Beaufort Sea, the concentrations of inorganic nitrogen (i.e. nitrate, nitrite and ammonia) at surface remain low throughout the year and the phytoplankton possibly depend on local recycling and the dissolved organic nitrogen (DON; e.g. urea, amino acids and primary amines) supplied by rivers. A large portion of the phytoplankton biomass is typically located within subsurface chlorophyll maxima (SCM). SCM productivity is possibly in balance with the episodic supply of nitrate across the halocline and/or the supply of ammonium and nitrate by local recycling and nitrification, respectively. Despite the importance of SCM for the food web and CO_2 fluxes, little is known about their structure, turnover and susceptibility to environmental variability and change.

2.6.1. Phytoplankton dynamics and nutrient fluxes

PI: Jean-Éric Tremblay (Department of Biology, Laval University)
Participants: Johannie Martin (9A and 9B) and Simon Pineault (9B) (Department of Biology, Laval University)

Objectives
The main goals of our subproject for leg 9 were to **(1)** establish the horizontal and vertical distributions of phytoplankton nutrients and the influence of different processes (e.g. mixing, upwelling and biological processes) on these distributions, **(2)** characterize the detailed vertical structure of chlorophyll-*a* with respect to irradiance, nutrient supply and physical structure, **(3)** experimentally assess causal relationships between phytoplankton productivity and the availability of light **(4)** determine the utilisation of different sources of inorganic and organic nitrogen by phytoplankton, and **(5)** assessed the role of the ice algae during the initiation of the primary production in the water column. Ancillary objectives were to calibrate the *SeaPoint* fluorometer and *ISUS* nitrate probe attached to the Rosette.

Methods
Samples for inorganic nutrients (ammonium, nitrite, nitrate, orthophosphate and orthosilicic acid) and urea were taken at all rosette stations (see Table 1) to establish detailed vertical profiles. Ammonium was determined immediately after collection using modifications of the manual fluorometric method (e.g. Holmes et al. 1999). Urea samples were either frozen or analyzed fresh using the method of Mulveena & Savidge 1992. The concentrations of nitrate, nitrite, orthophosphate and orthosilicic acid were determined on fresh samples using an Autoanalyzer 3 (Bran+Luebbe) with colorimetric methods adapted from Grasshof (1999).

Samples for the natural abundance (Table 1) of ^{15}N and ^{13}C in particulate organic matter were taken from ice-core (bottom part; 10 cm), ice-water interface, at 5 m and at the chlorophyll maximum (30 m if no maximum were observed). Volumes ranging from few millilitres (for ice samples) to 12 to 20 litres (for water samples) were filtered onto 24 or 47 mm pre-combusted GF/F filters and the filters were desiccated at 60°C in a drying oven. These data will be used for nitrogen uptake calculations and to assess the nitrogen status of phytoplankton communities.

The relationship between light and the uptake of C and N by phytoplankton (light-gradient incubation in Table 1) from the chlorophyll maximum was assessed using dual labelling with stable isotopes of C and N in four light-gradient modules (10 light intensities). Temperature was maintained at *in situ* levels with a chilling circulator. Samples from all modules were spiked with ^{13}C-bicarbonate; two modules received saturating additions of ^{15}N-nitrate, ^{15}N-ammonium (or ^{15}N-urea, or ^{15}N-nitrite), and the other two trace additions. Incubations were terminated by filtration onto 24-mm GF/F filters. All filters were desiccated at 60°C and stored dry for post-cruise determination of isotopic enrichment and particulate organic carbon and nitrogen.

SetCol protocol (Bienfang 1981) was carried out on water collected at the chlorophyll maximum (or 30 m) at the stations where incubations were performed to measure the sinking rate of the micro algae cells. Fractions from the top, the middle and the bottom part of the column were filtered on GF/F filter and extracted with acetone to determine the chlorophyll concentrations. Samples for the taxa composition were taken in the top, the middle and the bottom fraction in a second column and were stored with acid lugol for a post-cruise analysis.

The effects of incubation treatments (variable nutrient additions and light conditions) on the photosynthetic characteristics of phytoplankton were assessed by Pulse Amplitude Modulated fluorometry (PAM; Heinz-Walz). Nitrate data were used to calibrate the ISUS nitrate probe. Calibration of the Rosette fluorometer was achieved by comparing the instrumentôs output with extracted chlorophyll *a* and PAM data.

2.6.2. Dissolved Inorganic Carbon System

PI: Helmuth Thomas
Participant: Elizabeth Shadwick, Department of Oceanography, Dalhousie University, Halifax, NS, Canada, elizabeth.shadwick@dal.ca

The oceanôs exchange of carbon dioxide with the atmosphere is governed by the biogeochemical cycling of carbon and physical processes throughout the water column, which determine the concentration of dissolved inorganic carbon in the surface waters. Of the seven relevant carbon system parameters, a minimum of two are needed to calculate the others and fully describe the inorganic carbon chemistry, over-determination of the system being beneficial. During CFL Leg 9, roughly 450 samples were analyzed for dissolved inorganic carbon (DIC) and total alkalinity (TA), yielding two of the relevant parameters.

Water samples were collected at full, basic and mooring stations in parallel with nutrients rosette. DIC and TA were sampled using 500 mL glass bottles which were rinsed and filled using a plastic tube. DIC samples were first to be taken from the Niskin bottles, (preceded only by dissolved oxygen). These samples were either analyzed immediately following sampling, or spiked with $HgCl_2$ and stored in the dark at 4°C to await analysis.

Since we were using the moon pool for rosette sampling during Leg 9A, the top 10 meters of the water column were missed. In addition to this, we found that the 10 meter samples were often contaminated. As a result, the final rosette sample was taken at depth of 12 meters, and surface water sampling took place on the ice at roughly the same time as the rosette sampling. Surface water samples were collected from a hole in the ice, at fast ice and drift stations. Water was collected using a small battery operated pump which was lowered hand to 7, 5, and 1 meter below the surface. Bottles were filled using standard methods on the ice and returned to the ship for analysis. A CTD cast to a depth of 12 meters was taken at surface water sampling sites.

At open water stations, surface water samples were collected from the zodiac at some nominal distance from the ship, with the location determined by the direction of the current. Water samples were collected using either the pump, or a small Niskin bottle. A CTD cast was also done either with a small Sea-Bird CTD, or using the light-profiler in co-operation with Team 2. These water samples

were analyzed and results compared with the 5 and 2.5 meter depth samples taken from the rosette to determine the effect of the ship on the surface water sampling from the rosette with respect to DIC and TA analysis. Broadly speaking, we observed a disturbance of the mixed layer by the repositioning of the ship ï affecting mainly the temperature and salinity of near surface samples ï apparent by a discrepancy in these parameters between the ship and zodiac values.

DIC and TA were analyzed on board using a VINDTA 3C (Versatile Instrument for the Determination of Titration Alkalinity) by Marianda. Total alkalinity was determined by titrating a volumetrically accurate sub-sample of seawater using HCl as a titrant. In the case of dissolved inorganic carbon, a volumetrically determined sub-sample of sweater was acidified with 8.5% H_3PO_4 to convert all inorganic carbon into gaseous CO_2. The CO_2 is then stripped out of the sample using ultra-pure N_2 gas, followed by transfer into the titration cell where total inorganic carbon is then detected using the coulometric method (Johnson et al., 1993).

In addition to water column sampling, an attempt was made to continue (to a lesser extent) the ice core and brine sampling work initiated by team 6 in Leg 4 and 5. To this end, one core was collected at each fast ice and drift station. The top, middle, and bottom 10 cm of the core were cut and placed in plastic Tedlar bags ï gas impermeable, with a clamp type seal and small spigot for withdrawing air or water. The core sections were laid out to thaw, then analyzed for DIC, TA, and conductivity. Brine was collected using a peristaltic pump, from core holes drilled to 4 different depths relative to the ice surface. Standard methods were used to fill 500 mL bottles which were then analyzed for DIC and TA.

River water samples were collected at both the MacKenzie and the Horton Rivers, and analyzed for DIC and TA. This was of particular interest, since TA can be used as a fresh water tracer. ï Measurements of alkalinity from these two different (end-member) freshwater sources should allow us to distinguish between freshwater input from sea ice melt and freshwater input from the Horton and MacKenzie rivers to the Arctic Ocean in the CFL sampling region.

2.6.3. Sediment traps and water column DOC and EPS

PI: Christine Michel (Freshwater Institute)
Participants: Amélie Sallon[1] (9A and 9B) and Rodd Laing[2] (9B)
[1] Université du Québec à Rimouski (UQAR)
[2] University of Manitoba

Objective:

To quantify organic material sinking export processes under the ice and open water.

Sinking export processes were estimated with the **particle interceptor traps** method. Short-term traps were deployed in open water and under ice. Trap contents were used to analyze elements such as: pigments (chl a + pheopigments), POC, PIC, PON, EPS, biogenic silica (BioSi), stable isotopes. Thorium measurements were done in collaboration with Kirk Cochran in the open water stations. Trap contents were used for identification and enumeration of phytoplankton cells and estimation of the number and the size of fecal pellets.

Water-column measurements of dissolved organic carbon (DOC) and EPS were accomplished as part of this sub-project as well.

Sampling :

2.6.4. Barium

PI: Helmuth Thomas
Participant: Elizabeth Shadwick, Department of Oceanography, Dalhousie University, Halifax, NS, Canada, elizabeth.shadwick@dal.ca

In the Canadian Arctic, barium (Ba) is mainly released from the North American continent and can therefore be used as a tracer for terrestrial freshwater input. Together with ^{18}O, a tracer for freshwater input from precipitation and ice melt, all freshwater sources to the Arctic can be quantified.

Throughout Leg 9, samples for barium were taken from the rosette parallel to samples for ^{18}O, at approximate depths 5, 10, 20, 50, 70, 100, 140, 200 and 300 m. Small plastic bottles (15 mL) were rinsed three times, then filled and spiked with 15 µl concentrated HCl. Sample bottles were then sealed with parafilm and kept for later analysis using isotope dilution mass spectrometry.

2.6.5. Bacterial and Archaeal diversity and enzymatic activity

PI: Jody Deming
Participants: Colleen T. E. Kellogg, ctebean@u.washington.edu and Shelly D. Carpenter, seashell@u.washington.edu; School of Oceanography, University of Washington, Seattle WA 98195

Introduction and Background

Our work on board the NGCC Amundsen during Leg 9 of the CFL project consisted of two parts ï one focusing on Bacterial and Archaeal diversity and enzymatic activity associated with particles in the photic zone (Part 1; in collaboration with Kirk Cochranôs lab at Stony Brook University in New York) and the second focusing on these particle-associated microbes and associated enzymatic activities once they leave the photic zone, with particular interest in nepheloid layers (Part 2).

Our collaboration with the Cochran lab seeks to examine the export of carbon in two polynyas on river-impacted Arctic shelves and, for comparison, with a non-river impacted polynya. The North Water was our river-free control (sampled in 2006 during the ArcticNet cruise) for both the Cape Bathurst Polynya (sampled this cruise as well as during the ArcticNet cruise in 2006) and the Laptev Sea Polynya off the Lena River (sampled in 2005 as part of the NABOS expedition). Climate warming may alter the cycling of carbon on Arctic shelves through permanent reductions in ice cover and increases in riverine discharge. These changes may lead to, at least initially, increases in the export of carbon to the slope and deep Arctic basins. As a result, it is critical to characterize present carbon cycling in these, and other, polynyas. In order to do this, we will be coupling geochemical and microbiological analyses in a joint effort to examine particle flux, the diversity of the microbes associated with these particles and their extracellular enzymatic activity (i.e. the rates at which certain components of the particles are being hydrolyzed). In each polynya, patterns in the vertical particle flux will be measured by Dr. J. Kirk Cochranôs group using a radionuclide approach employing the natural radionuclide, ^{234}Th. Samples for this analysis were collected using large volume in situ pumps fitted with a 70 εm and 1 εm filter to represent the ósinkingô and ósuspendedô particle fractions, respectively. These filters will be also used by the Deming Lab Group to measure the extracellular enzymatic activity (EEA) associated with the different size fractions and the associated microbial diversity. Ultimately, this collaboration will allow for a better understanding of the different particle fluxes in river-impacted and river-free polynyas, the diversity of microbial communities associated with these different particle size fractions and origins (terrestrial versus marine), and the associated microbial enzymatic activity. Since all work is being done on the same filter set we expect to better understand the export of carbon in the aforementioned Arctic polynyas and which microbes contribute to its attenuation with depth. This knowledge will better equip us to understand and predict how carbon export may change as the Arctic continues to warm.

The second part of our project examines microbial diversity and particulate organic matter (POM) composition as it leaves the photic zone and its eventual fate. We are interested in how POM composition is transformed after it leaves the photic zone as well as how microbial diversity and enzymatic activity change below the photic zone, thereby examining the importance of microorganisms in altering sinking POM in the Arctic Ocean. By altering POM composition and concentration, microbes affect the food source for the benthic communities and the amount of carbon eventually available for sequestration in the deep Arctic Ocean. We have a particular interest in nepheloid layers as mechanisms for transport of POM off Arctic shelves and sampled them whenever observed in the water column. Nepheloid layers may provide a second chance for microbial degradation of recently deposited POM before it is sequestered in the deep ocean, ultimately affecting the extent of carbon sequestration in the Arctic Ocean. As this part of our project focuses on POM after it leaves the photic zone, we sampled at the chlorophyll max, the bottom and at one or two depths in between these two depths (generally approximately halfway between the chlorophyll max and the bottom). Again, as described above, we were interested in comparing microbial activity and diversity on terrestrially-derived and marine-derived particles and we believe that the samples taken during CFL

Leg 9 will allow us to adequately address this question. We believe this important as Arctic shelves, especially the Mackenzie Shelf, are commonly a mix of these two types of particles and microbial degradation of these particles types likely differs, affecting the composition of material eventually sequestered in the deep ocean.

Methods

Part 1:

In-situ pump samples ï Following deployment and recovery of in situ pumps by the Cochran lab, the pump heads from each depth containing one large 70 εm Polypropelene filter and one 1 εm microquartz filter were immediately taken to the 2°C cold room. They were first halved, with one half used by the Deming lab and the other by the Cochran lab. The Deming lab half was cut in half again (two quarters of the total). One quarter was used for extracellular enzymatic activity (EEA) measurements, described in greater detail below, and the other was sectioned into five parts. One filter piece was placed into a microcentrifuge tube and stored at -80°C for DNA analyses upon return to Seattle. The remaining four pieces were frozen for analyses of particulate lipids, amino acids and carbohydrates as well as ŭ^{13}C of POM.

Part 2:

Size fractionation of water samples ï In order to obtain different size fractions of particles and associated Bacteria and Archaea, 10 L of water, collected from niskin bottles, were filtered via a peristaltic pump through an in-line, size-fractionation set-up in a 2°C cold room. The water was first passed through a 60 εm nylon mesh filter, then through a 1 εm polycarbonate filter and finally through 0.22 εm durapore Sterivex filter. The >60 εm fraction is operationally defined as the ósinkingô particulate fraction. The 60-1 εm fraction contains the ósuspendedô particles and the 1-0.22 εm fraction contains free-living Bacteria and Archaea. Samples will be analyzed for Bacterial and Archaeal diversity in the University of Washington School of Oceanography labs upon completion of Leg 9.

In addition to size fractionation for examination of Bacterial and Archaeal diversity, we also size fractionated 4ï 10 L of water for measurements of extracellular enzymatic activity (see below) and for analyses of particulate organic matter components (particulate carbohydrates, amino acids and lipids) as well as stable carbon isotopic analyses (ŭ^{13}C). For each of these samples, only the >60 εm and 60ï 1 εm fractions were collected for analyses, with the exception of particulate lipids, where the free-living fraction (1ï 0.2 εm) was also collected. Due to limitations in the amount of water we could take, only single samples were taken for each of these analyses.

Extracellular enzymatic activity (EEA) - To estimate enzymatic hydrolytic rates of organic matter, extracellular enzymatic activity was measured using fluorescently tagged substrate analogs (Huston and Deming, 2002). Protease, chitobiase and carbohydrase activities were estimated using L-leucine 7-amindo-4-methylcourmarin (MCA-Leucine), 4-methylumbelliferyl-*N*-acetyl-ß-D-glucosaminide (MUF-G), and 4-methylumbelliferyl-ß-D-glucoside (MUF-B) respectively. Lipase activity was also estimated on some samples using MUF-oleate. Substrates were added to samples at saturating concentrations, determined on board using water from different sampling locations. At each station, 10 L of water from each depth was size-fractionated as described above. Following filtration, filters were resuspended in 40ï 50 ml of 0.2 εm filtered seawater from the same depth and station. This solution was then aliquoted into glass culture tubes for each enzyme type and respective substrates were added to a final concentration of 200ï 250 εM. Fluorescence was measured using a Turner Fluorometer over a series of time points to estimate EEA (change in fluorescence over time): with greater EEA, more fluorescent tags are released from the substrate analogs. EEA was measured at each station and depth sampled, and results were obtained shipboard.

Bacterial abundance estimates ï From each depth sampled, duplicate 15ï 50 ml samples were fixed with 0.2 um-filtered 37% formaldehyde to a final concentration of 2% formaldehyde. In order to estimate bacterial abundance associated with different size fractions of POM (discussed above) samples fixed were either whole seawater, <60 εm or <1 εm filtered. Fixed samples were stored at

2ï 4°C and will be stained with DAPI and acridine orange and analyzed microscopically upon return to the University of Washington.

Water column chemistry ï Water from the Niskin bottles was also collected to estimate chlorophyll *a* concentrations, particulate organic carbon and nitrogen and suspended particulate matter (SPM) to obtain a better understanding of particle-related characteristics of the water column. Following sample collection, water was brought back to the 2°C cold room. Duplicate samples of 500 ml from each size fraction discussed above were filtered onto precombusted GF/F filters for both chlorophyll *a* and POC/PON samples. These filtered were folded and placed in precombusted foil pouches, frozen at -20°C and will be analyzed back at the University of Washington labs. Duplicate 2 l samples were filtered onto precombusted, preweighed GF/C filters for estimation of SPM. These filters were placed in small 47 mm Petri dishes and stored at -20°C. They will be dried and reweighed back at the University of Washington for an estimation of SPM.

All of these analyses will allow for a comparison between EEA and community diversity obtained via large volume (in situ pump) and small volume (in-line, peristaltic pump) filtration. The in situ pump samples focuses on material in the photic zone while our smaller volume filtration focuses on the changes in this material and the microbial community associated with it once it leaves the photic zone and reaches the seafloor. As the bulk of our measurements are done back at our labs at the University of Washington, we do not have any results to report at this time.

Sample Stations and Collections

Figure 1. Map shows stations sampled by the Deming lab. At stations denoted by the white placemark, only samples for Part 2 of our project were collected. At stations denoted by the yellow placemark, samples for both Part 1 and 2 of our project were taken. At stations denoted by the orange placemark, only samples for Part 1 of our project were collected. Note: not *all* station labels are shown on this map, see following map for more detail.

Figure 2. Map zoomed in on stations visited by the Deming lab in Franklin and Darnley Bay. Station placemarkers denote the same meanings as described in Fig. 1.

2.6.6. ^{234}Th-derived POC fluxes and extracellular enzymatic activitiy

Participants: J. Kirk Cochran, Alisha Renfro (Leg 9B) and David Hirschberg (Leg 9A), Marine Sciences Research Center, School of Marine and Atmospheric Science, Stony Brook University, Stony Brook, New York 11794-5000 USA

Project Overview:
This project is collaborative with Jody Deming (University of Washington; represented by Colleen Kellogg and Shelly Carpenter on Leg 9). We are using the natural radionuclide ^{234}Th to determine POC fluxes in the water column and Demingôs group is measuring extracellular enzyme activities on particles collected with our in situ pumps (see Deming cruise report for more details).

Sampling:
After setting up our gear, sampling began on leg 9A. We collected samples of two types: 1) Small volume (2 L) water samples from rosette casts for measurement of total ^{234}Th (generally sampled at 0, 10, 25, 50, 75, 100, 125, 150 m) and 2) Particulate samples (>70 µm and 1-70 µm) obtained by deployment of four in situ pumps that filter 150-450 L of water at depths of 25, 50, 75 and 100 m. Table 7 shows the stations that were sampled.

Table 7. Stations sampled during leg 9.

Sample Processing:
Thorium was co-precipitated with manganese oxide from water samples and the precipitate was filtered onto 25 mm microquartz filters. The filters were counted for ^{234}Th beta activity using a low background beta counter. Particulate samples from in situ pumps were split with Demingôs group (50/50). For the >70 µm fraction (collected on polypropylene mesh filters), particles were rinsed off the filter, re-filtered onto microquartz filters, dried and mounted for beta counting. The 1 µm microquartz filter was dried and ten 20 mm punches were taken and mounted for beta counting. All samples were counted at least twice during the cruise to monitor the decay of ^{234}Th (half-life = 24 .1 days). Final work-up of ^{234}Th data will take place at Stony Brook University.

2.6.7. Marine microbiology group

Participants: Dan Nguyen, Maranger team ï Université de Montréal (leg 9a) and Gabriel Maltais-Landry, Maranger team ï Université de Montréal (leg 9b)

Introduction
Microorganisms are a heterogeneous group that include representatives of the three kingdoms of live, Archaea, Bacteria and Eukarya. These organisms drive biogeochemical processes in the ecosystem. Autotrophic microorganisms are the base of the Arctic trophic web, which comprises 7 orders of size magnitude, ranging from the smallest cell of less than 1 µm to the largest mammals. All of these organisms are strongly influenced by annual cycles of light, temperature and ice cover in terms of the composition and activity of the species present.

How microbes use organic and inorganic matter and how this influences other components of the food web? This knowledge is needed to better predict the consequences of natural or anthropogenic changes on these trophic dynamics. This will also help us to evaluate the systemôs ability to buffer these changes at short and long timescales.

Objectives
The measurements completed during this leg covered the work of 4 teams headed by Corina Brussard, Connie Lovejoy, Roxane Maranger and Carles Pedrós-Alió. We aimed to determine the diversity of species present and the importance of the biogeochemical processes driven by these organisms during the spring season.

The first specific objective of leg 9 was to maintain the intensive sampling for bacterial respiration started during leg 8b, to confirm the results obtained during leg 8 for both water column and ice cores. Secondly, we intensified nitrous oxide measurements to gain a better spatial resolution of the production of this gas. We focused on these two aspects (bacterial respiration, N_2O) as they are the most novel of our sampling protocols.

Sampling
The details of the stations sampled and measurements performed can be found in Table 8. The following variables were measured:

1. **Molecular genetics and gene expression:** Samples for DNA and RNA were collected once a week at 4 different depths. Six l seawater samples were prefiltered through a 50 µm mesh and then separated into ólargeô and ósmallô DNA fractions by filtration through a 3 µm and then a

0.2 µm polycarbonate filter. After collection samples were stored at -80 ºC until processing in the Lovejoy laboratory in Université Laval.

2. **Chlorophyll concentration:** Samples for chlorophyll analyses were taken once during leg 9. For each sample, one liter of water was filtered through a Whatman GF/F filter for microorganisms larger than the nominal pore size of 0.7 µm. In addition, 3 µm prefiltered obtain the small fraction, which was finally filtered through a Whatman GF/F filter. After filtration, the filters were stored overnight at -20ºC. Subsequently, the filters were introduced in acetone 90% and placed in a refrigerator, in the dark. After 24 hours, the fluorescence of the extracts, before and after acidification with 3 drops of 5% HCl, was determined by means of a Turner TD-700 fluorometer.

3. **HPLC:** Samples for High Pressure Liquid Chromatography (HPLC) analyses were taken once during leg 9. Two fractions were collected, one for the total fraction (down to 0.7 µm) and one for the small fraction (from 3 µm to 0.7 µm). Samples were stored at -80 ºC and will be analyzed at Laval University.

4. **Virus:** See report of Evans and Brussaard leg 9.

5. **Organic matter:** Using pre-combusted GF/F filters (47 mm diameter) in a passive filtration system (by gravity) samples for dissolved organic carbon (DOC), total organic carbon (TOC), amino acids and carbohydrates were taken once during leg 9a. Samples without filtration for total phosphorus determination were also collected.

6. **Bacteria and Archaea abundance:** Microscope preparations for bacterial abundance estimations were prepared by filtering a small volume of water (20ml) fixed with formaldehyde and staining with DAPI. Microscopy slides were prepared once a week at 6 different depths. Slides were frozen (-20°C) until counting on a epifluorescence microscope. Bacterial preparations were also obtained throughout the cruise on a less regular basis (e. g. ice cores). Slides for heterotrophic nanoflagellates (fixed with glutaraldehyde) were also prepared on a weekly basis.

7. **Ciliates:** Samples for ciliates abundance and diversity were collected during protocol 10, preserved using a Lugol acid solution, and will be analyzed off the ship.

8. **FISH – eukaryotes & CARD-FISH – Bacteria and Archaea:** Fluorescent In Situ Hybridization samples were collected once a week at 6 different depths, and on a less regular basis for other stations. Samples were stored at -80 ºC until analysis off the ship.

9. **MarFISH – bacteria and archaea:** Incubations with ^{3}H-labeled leucine and ^{14}C-labeled bicarbonate were carried out to detect active prokaryotes in the uptake of these substrates at two depths (surface and base of the nitrocline). Leucine incubations lasted for 8 hours and bicarbonate incubations lasted for 24h always in the dark. After fixation, samples were filtered and filters stored at ï 80 to be analyzed on land. In combination with the FISH technique this can give information on the phylogenetic identity of these active microorganisms. Besides the MarFISH incubations, samples were incubated with ^{14}C-labeled bicarbonate (at a lower concentration) to measure bulk bicarbonate uptake by bacteria and archaea in the dark. These samples were incubated for 24 hours and subsequently filtered. The filters were exposed to HCl fumes overnight, and embedded in cocktail for the scintillation counter measurement. This measurement was only carried out for leg 9a as we ran out of ^{14}C labeled bicarbonate.

10. **Bacterivory – FLBs grazing**: In order to acquire values of ingestion rates of bacteria by heterotrophic eukaryotes, Fluorescent Labelled Bacteria (FLB) obtained from a culture of *Brevundimonas diminuta* were used on bacterial grazing experiments. Triplicates and a 0.2 µm seawater filtered control with 10^5 cells/ml added were used. Samples for flagellates and

bacterial microscopy observation and for bacterial production were collected at the beginning and after 48 hours of incubation at seawater temperature (cold-room). This experiment was conducted once during leg 9.

12. **Bacterial production:** Bacterial production rates were measured at six depths once a week using the leucine incorporation method (^{3}H labelled leucine) with 4 hours incubation at in-situ temperature followed by readings on the shipôs scintillation counter. Samples were also taken on an irregular basis for other stations and projects (e. g. ice cores).

13. **Respiration:** Bacterial/community respiration rates were measured using the FIBOX, which measures O_2 depletion in time using sensors glued in 500ml Erlenmeyers. The consumption of O2 in time can be converted in CO2 production to compare carbon respiration rate to bacterial carbon production rates. Each experiment lasted for about 15 days and oxygen measurements were made every 1-2 days. The erlenmeyers were kept in the dark inside a cooler in a cold room.

14. **ETS:** Due to the low respiration rates in Arctic waters, a back-up method was also used to obtain respiration rate surrogates via ETS (Electron transport system activity). This is achieved by filtering a large quantity (8L-10L) of water on GF/F filters to collect live cells and freeze them (-80°C) as quick as possible. These will be analyzed (enzymatic activity) off the ship.

15. **N_2O in the upper water column:** Dissolved N2O measurements were carried out using the headspace equilibration method with 1.1 L of seawater. 3 samples were taken from 3 to 8 depths on a more or less daily schedule. These will be analyzed off the ship for N2O on an electron capture detector (GC).

2.7. Team 8

PI: Gary Stern (DFO, Freshwater Institute)
Participants: Debbie Armstrong (University of Manitoba), Alexis Burt (MSc student, University of Manitoba), Jeff Latonas (MSc student, University of Manitoba), Fiona Wong (Environment Canada, Toronto), Allison MacHutchon (DFO, Freshwater Institute), Joanne Delaronde (DFO, Freshwater Institute)

General objective
The question this project hopes to answer is how climate variability in physical forcing and the biogeochemical response to this primary forcing will affect hexachlorocyclohexane (HCH) and mercury (Hg)/methyl mercury (MeHg) contaminant cycling. Ultimately, we propose to relate changes in delivery and biogeochemical cycling of these contaminants to their levels in fish, marine mammals and the people who consume these tissues as part of their traditional diets.

An additional sampling campaign was undertaken during ArcticNet and CFL 2007-2008. The program is designed to obtain a detailed picture of PFOA (perfluorooctanoic acid) and PFOS (perfluorooctane sulfonic acid) concentrations in near shore and open ocean sites in the Canadian arctic.

2.7.1. Organic Contaminants

Hexachlorocyclohexane (HCH)

Technical HCH is a mixture of several isomers, the most abundant being α-HCH (60-70%), γ-HCH (5-12%) and β-HCH (10-15%). Technical HCH and pure γ-HCH (lindane, pesticide active isomer) have been used for over 50 years and are now ubiquitous in water throughout the northern hemisphere with the highest levels found in the surface water layers near pack ice in the Arctic Ocean.

Technical HCH was banned or heavily restricted by China, the former Soviet Union and India between the mid-1980s and 1990. Concentrations of α-HCH in arctic air responded quickly to these large-scale usage changes and declined by an order of magnitude from the early 1980s to mid-1990s in steps that closely matched global usage and emission estimates. As a consequence, the direction of net gas exchange in arctic waters reversed from deposition in the 1980s to air-water equilibrium or volatilization in the mid-1990s.

The α-isomer is the prominent in Arctic air, water, biota and soil, and moves northward via cold-condensation, a process whereby the contaminant evades into the atmosphere, drifts with atmospheric currents, and condenses in colder climates where at colder temperatures increasingly favours the water and extensive ice cover inhibit further evasion. Hence the contaminant accumulates disproportionately in the Arctic.

HCH water sampling
Water (4L) was collected using the rosette and using a pail or Niskin sampler for surface water collection at several stations. Where feasible, transects across water bodies were collected. In the aft lab, water was pumped through a glass-fibre filter followed by an ENV+ solid-phase extraction (SPE) cartridge using peristaltic pumps. Filters and cartridges were frozen and shipped to Fisheries and Oceans Canada, Winnipeg (DFO-Winnipeg). Salinity and ^{18}ŭO samples were also collected at each site and depth where HCH samples were taken. Salinity samples were analyzed onboard using the salinometer. ^{18}ŭO samples were stored at 2ºC and shipped to DFO-Winnipeg. ^{18}ŭO analysis will be performed at Fisheries and Oceans Canada, Sidney.

During Leg 9, water profiles (depths of, generally, surface, 5m, 10m, 25m, 50m, 100m, 200m, bottom) were sampled at stations D45, D34, F7, F8, FB01, FB05, HR01, 405B, 410, 416, 420, 421, 434, 435, 1100, 1110, 1200, 1208, 1216, 2010, 6006.

Surface water only was sampled at the Horton River delta, Mackenzie River delta and two meltponds at F8.

HCH air sampling
The air sampler was set up on the bow of the ship on the starboard side of the foredeck. Air sample collection coincided with water profile and zooplankton collection stations. Samples were collected on a glass fibre filter and polyurethane foam (PUF) for analysis of organic contaminants. Air sample collection times ranged between 4 and 7 hours. Filters and PUFs were frozen at -20°C and shipped to the Fisheries and Oceans Canada, Winnipeg for HCH analysis.

During Leg 9, air was sampled at stations D45, D34, F7, F8, FB01, FB05, HR01, 405B, 410, 416, 420, 421, 434, 435, 1100, 1110, 1200, 1208, 1216, 2010, 6006.

HCH biotic sampling
The main purpose of this study is to link physical and biological processes to mercury/HCH levels in the food web and to target the pelagic food web biomagnification and bioaccumulation of HCH and mercury with stable isotopes and fatty acids. Thus, all biological samples collected will be measured for HCHs, total mercury and MeHg along with stable isotopes to place organisms into their associated trophic levels.

Zooplankton
Zooplankton samples were collected at open water and ice stations in conjunction with water and air sample collection. Zooplankton was sorted into families, or to genus and species where possible, placed in scintillation vials and Whirlpak bags and frozen for HCH, stable isotopes and fatty acids analyses. See data report subsection for teams 4 for information on zooplankton species collected, stations sampled and collection methods.

Polychlorinated biphenyls (PCBs)

General Objective
As a result of extensive studies over the past 30 years, much has been learned about traditional contaminants like PCBs and their pathways, processes and effects in the Canadian Arctic. One of the only areas remaining as a major knowledge gap is Arctic seawater. PCB concentration data for Arctic seawaters are rare, largely because opportunities to collect the samples are rare, and also because it is challenging to sample and analyze PCBs at the low concentrations that occur in Arctic seawater without contamination or other biases. As we learn more about these challenges, increasingly it looks like some of the data collected in the past ï including some in the Canadian Arctic ï may be incorrect.

The goal of this project is to obtain new, trustworthy measurements of dissolved PCB concentrations in Canadian Arctic Ocean seawater, guided by recent developments in our understanding of the challenges associated with this work, and how they can be overcome.

Equipment preparation and sampling techniques
Our groupôs experience with sampling Arctic seawater for contaminants in the course of the Canadian Arctic Shelf Exchange Study (CASES) and ArcticNet cruises has made us very cognizant of the challenges of this kind of sampling generally and also more specifically, for the conditions aboard Canadian Arctic research vessels.

Ultra-clean procedures were considered from the time that sampling materials (XAD-2 resin and glass fiber filters) were first prepared, through their storage and handling in the field and during and after sample collection. In preparation for sampling, XAD-2 resins were rigorously cleaned, proofed and

packaged at AXYS Analytical Services Ltd. The filters were pre-combusted, stored in baked aluminum envelopes and vacuum sealed in plastic. New Teflon tubing and connectors as well as the pump filter plates were cleaned with hexane and vacuum sealed in plastic. These components were prepared at the Freshwater Institute, DFO, Winnipeg. The cleaned materials were stored on the ship in a vacuum seals bags inside a clean cooler to minimize their contact with the shipôs atmosphere and other potential contamination sources.

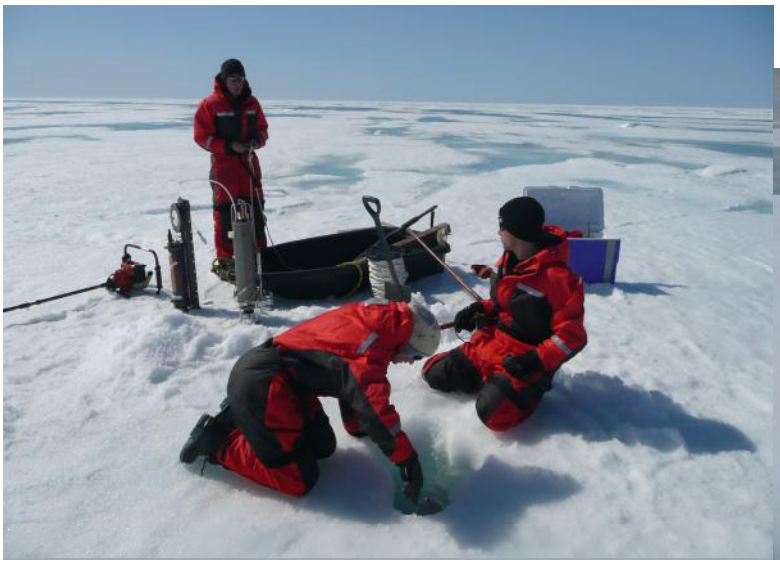
Two in situ pump systems (Infiltrex and SeaStar) were deployed beneath the sea ice to a depth of 15 m thus sampling Arctic Ocean seawater from the sea ice (rather than a ship) as a platform. The sampling area was upwind and approximately 500 m away of the ship to reduce the effects of the ships atmosphere.

The systems are equipped with glass fibre filters to collect suspended particulates (and associated PCBs) and stainless steel columns containing XAD-2 resin, which extract dissolved PCBs. During leg 9A the project was limited by the number of pre-cleaned columns available. Of the five columns, two were treated as procedural blanks and three as samples.

Two blanks were obtained by passing approximately 1-L of seawater through each pumping system. The expected blank levels for filters and XAD-2 resin columns are in the order of 3-8 pg absolute.

Samples consist of between 250-400 L of seawater**.** (400-600 L would have been preferred.) Assuming that PCB concentrations in Canadian Arctic seawater are similar to recently reported values for the European Arctic (e.g., $\Sigma PCBs_{15}$=0.54-1.96 pg/L, PCB congener 52 concentrations = 0.10-0.24 pg/L; (Gustafsson et al., 2005)), sample volumes of 400-600 L should produce readily quantifiable PCB congener concentrations (40-120 pg absolute).

After the required volume of water was sampled, the columns and GF/F were placed in ziploc bags, sealed and returned to the ship where they were vacuum sealed. The columns were stored at 2ºC and the GF/F at -24ºC.



Preparing pumps and site for deployment.

SeaStar high volume pump with XAD column and filter attached.

Samples collected

Date begin	Total pumping time (hours)	Sample code	Column ID	Station	Total Volume (L)	Pump type	Location	
							Lat (N)	Long (W)
08-Jun-08	0.12	CFL08-HV-0005	4415-31	F7	2.35	Infiltrex	69º 49.63	123º 37.85

15-Jun-08	59.17	CFL08-HV-0009	4415-35	FB05	529.81	SeaStar	69º 57.38	125º 52.01

All samples and blanks pumped at a rate of 150 mL min^{-1}.

PCB congeners will be analyzed at AXYS Analytical Services Ltd. by high-resolution gas chromatography/mass spectrometry (US EPA method 1668A). Samples are analyzed in batches of 12-15 or less and a blank, spike and/or duplicate is analyzed with each batch.

Currently Used Pesticides (CUPs) and Perfluoro Compounds in the Atmosphere

The fate of pesticides applied to agricultural fields is of great interest because they are manufactured to be toxic to biota and some organisms. Currently used pesticides (CUPs) are generally more volatile and less persistent than the older style organochlorine pesticides, such as HCHs, but they can still undergo atmospheric transport through volatilization and deposition followed by reemissions. They ultimately make their way to sensitive ecosystems including the Canadian Arctic. CUPs include: dacthal, chlorothalonil, endosulfan and Chlorpyrifos, which have been reported in Arctic air (Hung et al., 2005; Jantunen et al., 2007, Shen et al., 2005; Pozo et al., 2006; Chernyak et al., 1996), seawater (Jantunen et al., 2007; Chernyak et al., 1996; Weber et al., 2006), sub-arctic/arctic lake water (Muir et al., 2004), snow (Hermanson et al., 2005; Chernyak et al., 1996) and fog (Chernyak et al., 1996). Perfluoro chemicals are emerging persistent organic pollutants which are found in a wide range of applications such as paints, packaging, lubricants, firefighting foams, stain repellents and cookware. They are found in Arctic where they accumulated in the food chain and in the atmosphere (Butt et al., 2007; Shoeib et al., 2006). There are is little known about their atmospheric levels in the Arctic.

During Leg 9B, air (~1200m^3, n=8) were continuously collected to determine occurrence and levels of CUPs. Air was drawn at a flow rate of 0.5 m^3/min, through a glass fiber filter (Whatman, Maidstone, England, 20.3 x 25.4 cm, EPM 2000, collects 99% of particles >0.3µm) followed by two plugs of polyurethane foam (PUF), each 8 cm diameter x 7.5 cm tall, that collect the gaseous phase. Surface water samples (n=8) of 30-40L were collected by using a bucket dropped to the side of the boat. The water is passed through a glass fibre filter (GFF, 142mm) followed by a column of XAD-2 resin (Amberlite, macroreticular styrene divinylbenzene copolymer, 20-60 mesh size, Rohm and Haas, Supelco, Bellefonte PA, USA, 1.5 cm i.d., 75 mL settled volume) to concentrate the dissolved fraction.

A separate set of air samples were collected for perfluoro compounds. Three ~350 m^3 air samples were taken with a PS-1 (Tisch Environmental, Village of Cleves, OH, U.S.A.) sampler, consisting of 7.6 cm diameter GFF followed by PUF-XAD-2-PUF plug sandwaich (6.8 cm diameter). These were collected for Mahiba Shoeib at Environment Canada, Toronto. Sampling will be continued in Leg 10.

α-HCH Flux Experiments

Hexachlorocyclohexanes (HCHs) are the most abundant organochlorine pesticides in Arctic air due to their facile atmospheric deposition in the cold environment and slow degradation rates. In the past two decades, there has been a reduction in primary emissions of technical HCH with an accompanying decline in atmospheric HCHs concentrations. As a result, a reversed direction of air-water flux from net deposition to net volatilization has been observed in some arctic regions. This study was carried out to determine the gas exchange of HCHs using gradients of HCH concentrations and enantiomer fractions (EF) of α-HCH, where EF = concentrations of (+)/[(+) + (ï)] enantiomers.

Air samples were collected at three heights above the surface water, at ~1m, ~6m and ~12m to determine the flux of α- HCH and its enantiomers. These samples were collected during full stations and at the community visit at Holman. There were a total of 8 sampling events. A modified PS-1 (Tisch Environmental, Village of Cleves, OH, U.S.A.) sampler was used consisting of 7.6 cm diameter GFF followed by one PUF plug (6.8 cm diameter x 4.2 cm). Sampling rate ranged from 70-115 ml/min which gave a sample volume of 60-100 m^{-3}. Parallel low volume water samples of 4L were also collected in duplicates. These low volume water samples were passed through a glass fibre filter (47mm) followed by a ENV+ (200mg, Jones Chromatography) SPE cartridge.

It is expected that α-HCH levels in air collected near the water surface is higher than those collected at 12 m above water. Similarly, EFs of α-HCH in air sampled closest to the water are expected to approach the nonracemic EFs in the surface water and tend toward more nearly racemic values with height.

2.7.2. Mercury

Rationale

Mercury (Hg) levels in marine mammals and fish are an ongoing concern in Arctic regions because of their inclusion in traditional subsistence diets among indigenous peoples in northern regions. Successful strategies to mitigate health impacts related to Hg in human diets require an understanding of both the social and cultural perspective of northern communities, as well as the natural environmental processes that lead to Hg in food resources. Our research on Hg in the Arctic is focused on determining the environmental processes responsible for the distribution and speciation of Hg in Arctic marine ecosystems, for the purpose of supporting the development of strategies to lessen the impact of Hg on human and ecosystem health.

Marine Water Column Sampling

During Leg 9 of the CFL Study, the Team 8: Contaminants group collected samples from the marine water column in Amundsen Gulf from 24 locations within the Amundsen Gulf and the Beaufort sea as well as three rivers: Horton River Estuary, Horton River and the MAcKenzie River (Table 1). Samples from the 10 m depth to the seafloor were collected with the ship-based Rosette sampling equipment in PVC ôNiskin-styleô sample bottles remotely operated from onboard the ship. Supplementary ôSurfaceô samples from 0 to 10 m in depth were collected by a PVC Niskin water sampling bottle (General Oceanics, Miami, Florida) from a hole or open lead within a few hundred meters of the ship and within three hours of the Rosette collection (Table 1). Within each profile, 11 to 20 different depths were sampled (including Niskin sampling), producing high resolution profiles for ótotal Hgô (Hg_T) and methyl Mercury (MeHg). At each depth sampled for Hg_T, water was also collected for ŭ^{18}O analysis in tightly sealed glass scintillation vials. After collection of ŭ ^{18}O samples, bottles were further sealed with parafilm and stored at 4°C.

Preliminary Results

Hg_T levels in the Amundsen Gulf measured during Leg 9 were very low, averaging roughly 1 pM (0.2 ng/L) throughout the water column. These values are comparable with the lowest concentrations of Hg_T observed in the global oceans (e.g., the Pacific and North Atlantic Oceans), and somewhat lower than those observed in coastal oceans and regional seas (e.g., the Baltic and the Celtic Seas, Hudson Bay). However, we were able to observe changes in the concentrations caused by the final ice /meltbreakup and influence of river inputs from the Horton and the Mackenzie River systems.

Table 5. Sampling Location and Date for Marine Water HgT Measurements During CFL Leg 9

Station	Date	Location	Bottom Depth (m)	Cast #
405b	June 10	Amun. Gulf	590	13

1110	July 12	Amun. G	94	162
D34	July 13	Amun. G	185	177

At open water stations, surface water samples were taken with the zodiac to avoid contamination from the ship. It was quite evident that the results from the Niskin sampling were lower in THg concentration. Of course, the Niskin must be cleaned and tested at both the spigot and the top of the Niskin before use.

Atmospheric Mercury

Three systems have been running constantly during Leg 9 for real-time atmospheric mercury speciation monitoring in the air. On Leg 9, these systems were monitored and operated by Jeff Latonas.

Mercury Speciation System (SN323)
This system includes a Tekran 1135, a Tekran 1130, a Tekran 1130 Pump, and a Tekran 2537B (SN323). It provides real-time atmospheric Hg measurements for gaseous elemental mercury (GEM; every 5 min), particulate mercury (Hg_P; every 2 hours) and reactive gaseous mercury (RGM; every 2 hours). The system was installed in Leg 5 and has been continuously working without major problems. There were no major interruptions of the instruments operation in Leg 9.

No Mercury depletion events were observed during leg 9; GEM, RGM, and Hg_p remained fairly constant throughout the period. The last of the depletion events were observed on leg 8 with the last one occurring on may 29th near the north eastern point of Banks Island. The predominant Hg 2+ species has continued to be RGM since May 6th.

The glassware in the 1130/1135 speciation unit was changed on June 20th including the RGM denuder, particulate mercury filter, and intake glassware. The unit was shut down on the 11th of July and the speciation unit was dismantled. A series of standard injections was performed on the 8th of July to confirm proper calibration of the instrument and results were good (within 5%). The 2537B (SN323) was then converted to sample only GEM for the remainder of the cruise. GEM sampling with this instrument began on July 12th.

Total Atmospheric Mercury System (SN051)
We are also monitoring Total mercury (Hg_t) through a Tekran 1105 arctic pyrozlyzer unit which heats the sample to 900°C before analysis by another Tekran 2537A (SN051). This unit was operating normally throughout leg 9. Total mercury concentrations remained fairly constant throughout the leg due to the absence of depletion events. Measurements were stopped on the 11th of July and the system

was dismantled. A series of standard injections was performed on July 8th to confirm calibration and the results were good.

Gaseous Elemental Mercury (SN071)
Alongside the speciation unit an additional Tekran 2537 was monitoring GEM (SN071). This unit was installed on May 20th during leg 8 and was operational until the 11th of July after which the Tekran 2537B (SN323) took over GEM measurements. GEM concentrations were constant throughout leg 9 and consistent with the total atmospheric mercury measurements from SN051. On June 20th the unit underwent maintenance which included replacing both gold cartridges and heaters. A series of standard injections was performed on July 8th to confirm calibration and the results were good.

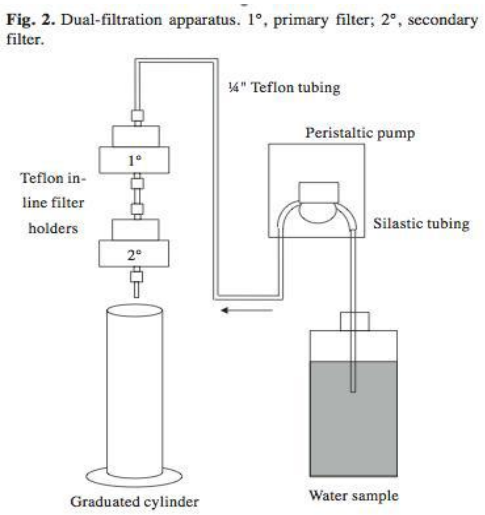
Mercury in Phytoplankton and Zooplankton

Algae (Hg, MeHg)
Phytoplankton samples were taken in conjunction with zooplankton tows. Samples were sieved through 710µm, 350µm, 150µm, 50µm and 20µm mesh and frozen. Samples were also preserved with lugolôs for speciation.

Phytoplankton was collected at stations F7, HR01, F7 open water, and 2010. At open water stations, phytoplankton was collected with a 20um mesh net (stations 405B, 1216, F7 open water, FB07 open water, 1200, 1208, and 6006). The rosette was used to collect phytoplankton at the chlo max (stations 405B, FB03, HR01, 1216, 1208, 6006, and 2010) these samples were filtered as below.

Under-ice algae was collected from the ice-water interface with a battery powered pump on a metre long under ice arm (stations F7 (x2), and 2010). These samples were filtered onto pre-combusted and weighed glass fibre filters (GF/F) for chlorophyll *a*, dry mass, and filtered in series with a clean set up for mercury, with a blank (see figure). The filters were frozen, and will be shipped to Winnipeg for further analysis.

Under-ice algae was also collected during the dive program using slurp guns and the same 20µm mesh net at stations F7 (x2), FB03, FB05, and FB07. These samples were also filtered as described. Ice algae was not collected as there was no more ice algae.



Filtration set up for algal Hg (exception: the peristaltic pump is between the filters and the waste container)

Sarah and Alexis collecting slurp gun samples at the dive program (photo by Shelly Carpenter)

Zooplankton

Zooplankton samples were collected during the leg. Various zooplankton families were collected using horizontal/oblique tows on the foredeck with a double Tucker net (500µm mesh) and vertical tows done with the monster net (4x200µm mesh nets). Samples were also collected from the using the zodiac at the ice edge, and from the dive hole with a ring net (200µm mesh), and from under the ice using a vacuum during the dive program (H. Hop).

Zooplankton was sorted into families, or to genus and species where possible, placed in scintillation vials and Whirlpak bags and frozen until they can be analyzed for THg, MeHg, stable isotopes and fatty acids. Common species found were *Calanus hyperboreus*, *Calanus glacialis, Paraeuchaeta glacialis*, *Sagitta elegans, Sagitta maxima*, *Themisto abyssorum*, *Themisto libellula*, Cnidarians, and Ctenophores. Some less common species found were *Cleone limacina*, *Limacina helicina*, *Hyperoche* sp., *Gammarus* sp., *Onisimus* sp., Euphasiids and one unidentified fish.

Zooplankton was collected at station F7 (x12), 405B, FB01, FB03, FB05 (x2), FB00 (x2), HR01 (x2), FB07, 1216, 1200 (x2), 1208 (x2), 434, 421, 435, 6006, 2010, and 410 for a total of 34 zooplankton hauls leg 9.

Special thanks to the Zooplankton Team members (Gerald, Stéphane, Samuel, and Helen) for hours of collecting and help sorting, and to the crew for their tireless support and encouragement. This project wouldn't be complete with out you!

Mercury in Ice, Brine and Snow

In order to study the cycling of Mercury in the Arctic environment, we need to understand how it moves through the barrier separating the atmosphere and ocean known as ice. Movement through ice is thought to be carried through the network of brine channels that are formed within the ice and the interaction of that brine with the water column with the onset of spring. Another important factor to consider is the impact of snow or deposition as a source from the atmosphere to the snowpack, ice column and directly into the ocean.

On leg 9 we collected ice cores, snow samples and brine/melt pond samples as much as possible to track the movement of mercury with these media. Samples of each were collected over varying time series at stations: F7, FB04, FB07 and 2010. The ice cores from stations FB07

and 2010 were processed, the remaining cores from stations D34 (leg 8), F7 and FB04 are in the portside chest freezer. These were not sampled due to a limited number of falcon tubes onboard.

All ice cores were cut into duplicates and each duplicate was scrapped with a freshly cleaned and tested ceramic blade. Both pieces were placed into separate zip lock bags and then stored in one larger bag to melt. When sampling, each individual zip lock bag was rinsed with MQ water over the area that would be cut and then sampled. A small amount was rinsed out and then the sample was collected. For example, a 5 cm piece of ice split would yield two 25 mL samples of water in the end. The scrapping was very clean, and the gloves were changed between each section of the core to be scrapped. This is essential to good reproducible results.

Snow samples and melt ponds were collected on a daily basis when possible.

Methyl Mercury

The form of mercury that accumulates within the foodweb is the organic form of mercury known as methyl mercury. We are interested in determining the pathways in which mercury (Hg) becomes methylated and to study the levels in the abiotic and biotic environments. We are up and running Methyl Mercury samples with our new and improved BrooksRand Automated system. The detector lamp needs to be changed at the beginning of each leg and possibly after travelling through heavy ice. The detector was quite stable this leg and we were able to analyse samples collected on leg 7: D29b as well as collect and analyse samples from nine stations including the Horton and MacKenzie rivers. We were able to reach the detection limit of the instrument in our sensitivity to 0.01 ng/L. Analysis time is approximately two days for 30 samples.

Sample depths are chosen based on the CTD profile from the rosette at the time of deployment. As the CTD goes down, it maps out the characteristics of the water column and the ñinterestingò depths are those where salinity, temperature and chlorophyll differ to identify different water masses of the water column. At all sampling events, both δO18 and THg samples were collected.

BrooksRand Automated MeHg system.

2. Team reports

2.1. Team 1

PI: Yves Gratton (INRS-ETE, 490, Rue de la Couronne, Québec)
Participants: Véronique Lago, Antoine Roy-Gobeil (INRS-ETE, 490, Rue de la Couronne, Québec)

2.1.1. CTD/Rosette

Objectives
Description of water masses and general circulation over a year in Beaufort Sea and Amundsen Gulf. Physical parameters were recorded using a ship mounted RDInstruments Ocean Surveyor ADCP (150kHz), and a rosette frame equipped with 24 bottles of 12 L.

CTD-rosette

Materials
The rosette frame is equipped with 24 bottles of 12 L and the following sensors:

Table 1: Sensors used on the Rosette

Photo	Item	Manufacturer	Type & Properties	Serial Number
	CTD	SeaBird	SBE-911 Sampling rate : 24 Hz	
	Temperature	SeaBird	SBE 3plus Range: -5°C to + 35°C Accuracy: 0.001	4204
	Pressure	SeaBird	Accuracy: 0.015% of full range	90584
	Conductivity	SeaBird	SBE 4C Range: 0 to 7 S/m Accuracy: 0.0003	2696
	Oxygen	SeaBird	SBE-43 Range: 120% of saturation Accuracy: 2% of saturation	0427
	pH	SeaBird	SBE-18 Range: pH from 0 to 14 Accuracy: pH 0.01	0444
	Nitrates	Satlantic	MBARI ISUS Range: 0.5 to 200 µM Accuracy: ± 2 µM	134
	PAR	Biospherical		4664

	SPAR	Biospherical		20147
	Fluorometer	Sea Point		2465
	Transmissometer	WetLab	Path length: 25 cm	CST-558DR
	Altimeter	Benthos		1061
	ECO fluorometer (CDOM)	Wet Labs	FL(RT)D Digital output resolution : 14 bit Analog output signal: 0-5V Range: 0.09-500ppb Ex/Em: 370/460nm	

Table 2: Sensors specifications

Parameter	Sensor		Range	Accuracy	Resolution
	Compagny	Instrument Type			
Attached to the Rosette					
CTD	SeaBird	SBE-9plus [1]			
Temperature	SeaBird	SBE-03 [1]	-5°C à +35°C	0.001°C	0.0002°C
Conductivity	SeaBird	SBE-4C [1]	0-7 S/m (0-70mmho/cm)	0.0003 S/m (0.003mmho/cm)	0.00004 S/m (0.0004 mmho/cm)
Pressure	Paroscientific	410K-105	up to 10 500m (15 000psia)[2]	0.015% of full scale	0.001% of full scale
Dissolved oxygen	SeaBird	SBE-43 [3]	120% of surface saturation[4]	2% of saturation	unknown
pH	SeaBird	SBE-18-I [5]	0-14 pH units	0,1 pH unit	unknown
Nitrates concentration	Satlantic	MBARI-ISUS 5T [6]	0.5 to 2000 µM	±2 µM	±0.5 µM
Light intensity (PAR)	Biospherical	QCP2300	1.4×10^{-5} to 0.5 εE/(cm^2·sec)		
sPAR	Biospherical	QCP2200	1.4×10^{-5} to 0.5 εE/(cm^2·sec)		
Fluorescence	Seapoint	Chlorophyll-fluorometer	0.02-150 µg/l	unknown	30
Transmissiometer	Wetlabs	C-Star	0-5 V	unknown	1.25 mV
Altimeter	Benthos	PSA-916 [7]	0 - 100 m	unknown	0.01 m
CDOM fluorescence	Wet Labs	FL(RT)D [7]	0.09-500ppb	unknown	14 bit

Notes: [1] Maximum depth of 6800m
[2] Depending on the configuration
[3] Maximum depth of 7,000m
[4] In all natural waters, fresh and marine
[5] Maximum depth of 1,200m
[6] Maximum depth of 1,000m
[7] Maximum depth of 6,000m

Method
Water was sampled according to each team requests. Here are examples of usual depths collected by them.

- *Nutrients* (Team 7; PI: Jean-Éric Tremblay): salinity of 33.1, chlorophyll maximum, 10, 20, 30, 40, 50, 60, 80, 100, 120, 140, 160, 180, 200, 250, 300 and every 100 m up to the bottom.
- *Nitrogen* (Team 7; PI: Jean-Éric Tremblay): surface and chlorophyll maximum.
- *DIC* (Team 6; PI: Lisa Miller): salinity of 33.1, 5, 10, 20, 30, 40, 50, 60, 80, 100, 120, 140, 160, 180, 200, 250, 300 and every 100 m up to the bottom.
- *Mercury*(Team 8; PI: Gary Stern): salinity of 33.1, 5, 10, 20, 30, 40, 50, 60, 80, 100, 120, 140, 160, 180, 200, 250, 300 and every 100 m up to the bottom.
- *doc/don* (Team 7; PI: Christine Michel): salinity of 33.1, 5, 10, 20, 30, 40, 50, 60, 80, 100, 120, 140, 160, 180, 200, 250, 300 and every 100 m up to the bottom.
- *DNA* (Team 7; PI: Connie Lovejoy): surface and chlorophyll maximum
- *CDOM* (Team3 ; PI: Pierre Larouche): 10, 25m and chlorophyll maximum while in the ice and 50%, 20% of light, chlorophyll maximum and 60m while in open water on primary production rosettes; 5m and middle of water column for other sampling.
- *Primary production*(Team 3; PI: Michel Gosselin): 10, 25m and chlorophyll maximum while in the ice and 50%, 30%, 15%, 5%, 1%, 0.2% of light, chlorophyll maximum, 75 and 100m while in open water.

Sampling locations
We focus on the Amundsen Gulf and the Mackenzie River.

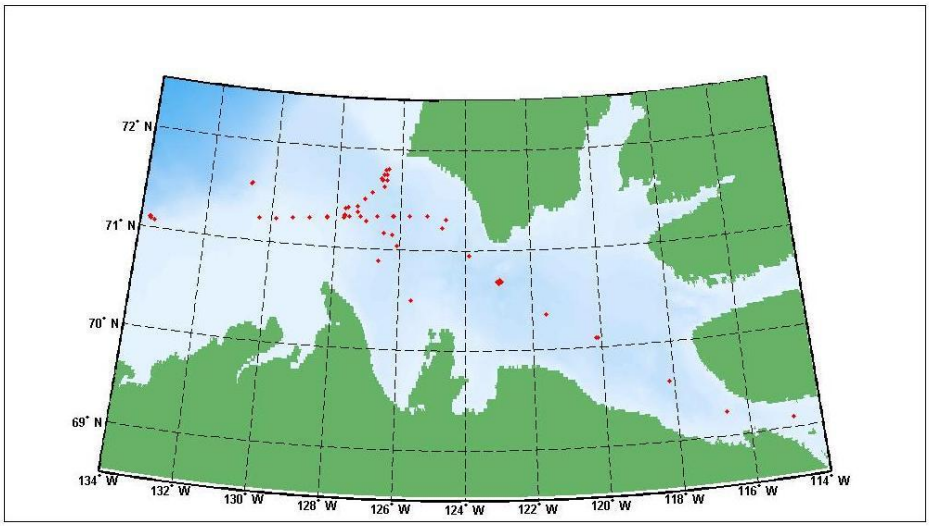

Figure 1: Positions of Rosette casts are shown as red dots.

Probes calibration

Salinity: Samples were taken on many casts with small bottles of 200 mL. They were analysed with an autosal GuildLine, model 8400B. Its range goes from 0.005 to 42 and its accuracy is < 0.002. The results were not really satisfying. The difference in between the salinity probe recordings and the samples was around 0.09. However, the conductivity probe has been changed a few times during the leg as a reaction to the bad results of the CTD

pH: Tests were done a few time using two buffers. The results are not satisfying. Results are as follow:
Buffer 4.01 gave from 7.68 to 6.07
Buffer 7.00 gave 7.13 and 6.91
Sea water is usually around pH=8, we can expect pH data to be over estimated.

Oxygen: Oxygen sensor calibration was performed using Winklerôs method and a Mettler Toledo titration machine. Reagent Blanks was performed once, results show that chemicals are still good (m<4). Oxygen have been sampled on three casts. Each time, we choose five depths of different oxygen concentration and sampled it three times. The results are not satisfying; the slope of comparison between the sensor and the samples was varying from 0.76 to 1.04. The results are nonetheless similar to what we got on leg 8 and 9 even after the oxygen probe has been changed during leg 9. Thus, the oxygen probe might have an offset that will need to be corrected.

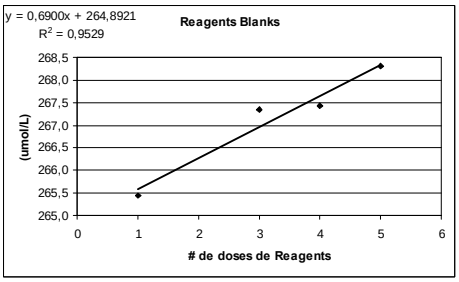

Figure 2: Reagents Blanks (m=0.69) measured during leg 0804 with the same chemicals on cast 148.

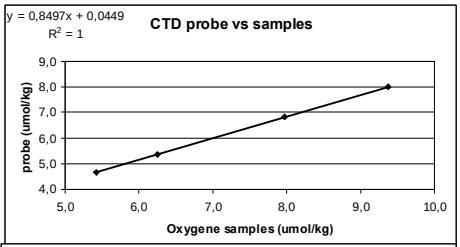

Figure 3: Relation between samples and probe recordings during cast #016 (m=0.8497).

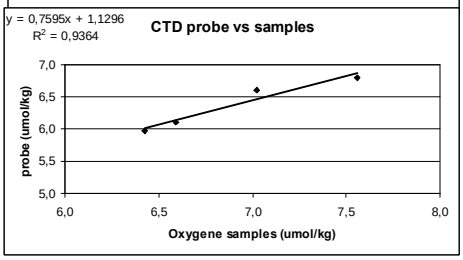

Figure 4: Relation between samples and probe recordings during cast #041 (m=0.7595).

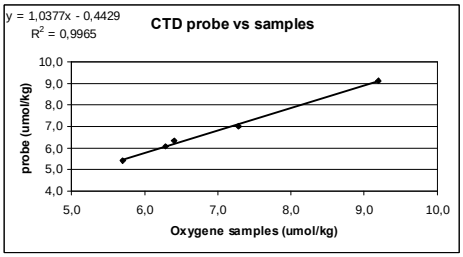

Figure 5: Relation between samples and probe recordings during cast #053 (m=1.0377).

Problems

- **Sensors**
  The sensors started to act strangely after a new fluorometer for CDOM has been installed on the rosette for cast 0805011. Then many tentative have been done to solve the problems, until all the communications with the CTD shut down. Then all the sensors and cables have been changed. Once the signal passed again, the pump stopped working deeper to 270m. The problems have been satisfyingly solved for cast 0805044, except for a few more problems with the carrousel for the bottles closure.
  The oxygen probe may have an offset.
- **Deck material (winch, A-frame, etc.)**
  No problem reported.

Available data

All information concerning the Rosette casts are summarized in the CTD Logbook. It includes cast and station numbers, date and time of sampling in UTC, latitude and longitude, bottom and cast depths, as well as the cast name and comments concerning the cast. A Rosette sheet was also created for every single cast. Information on this sheet includes the type of parameter sampled and weather information. For every cast, data recorded at the moment of bottle closure were averaged and recorded in the so-called ôbottle filesô. Averaged data are those recorded between 3 seconds before bottle closure and 7 seconds after the closure. It includes the bottle number, time and date, pressure, temperature, salinity, transmissivity, chlorophyll, oxygen, irradiance and pH measurements. All those files are available on the ôSharesô.

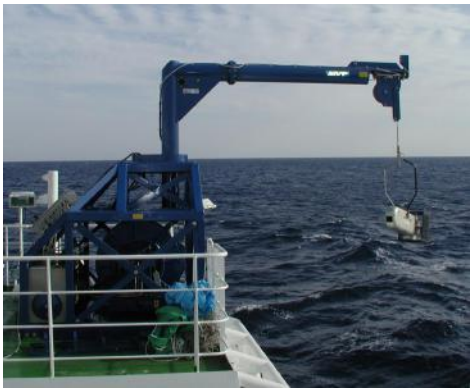
- Rosette sheets and the CTD logbook : Shares\Leg10\Rosette_CTD\logs
- Bottles files : Shares\Leg10\Rosette_CTD\bottle_data
- Plots of every cast including salinity, temperature, oxygen, transmissometer, nutrients, fluorometer and irradiance : Shares\Leg10\Rosette_CTD\plots

A total of 064 casts were performed between July 17th, 2008 and August 7th, 2008.

Self Contained Autonomous MicroProfiler (SCAMP)

Unfortunately the SCAMP was out of commission in leg 10.

MVP (Moving Vehicle Profiler)



The Moving Vehicle Profiler (MVP) is basically a towed CTD (with fluorescence and dissolved oxygen sensors). The MVP has been used only once with the ship stopped, just as a regular CTD, to compare with the profiles given by the CTD attached to the rosette.

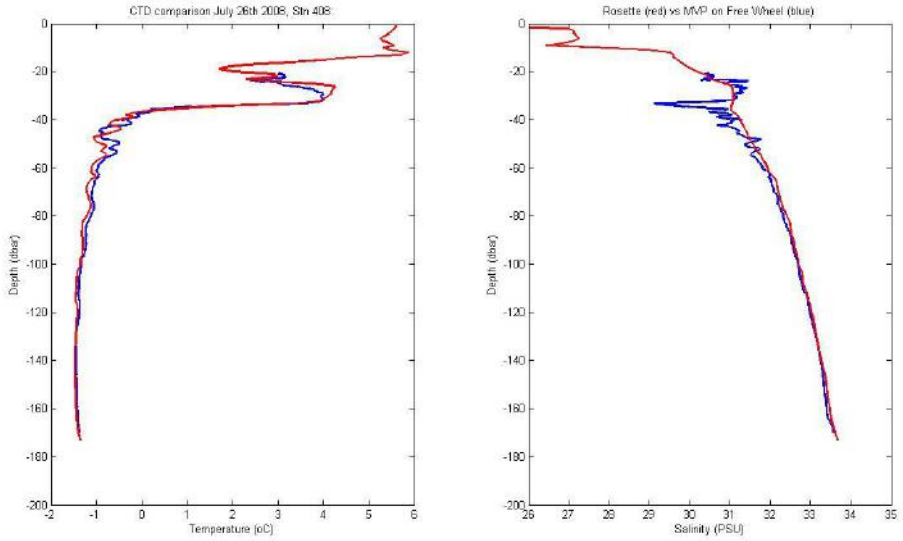


Figure 5: Comparison of CTD profiles from the Seabird SBE-911 attached to the rosette (red line) and the Brooke Ocean in the MVP (blue line).

ADCP

Data have been recorded continuously using a ship mounted RDInstruments Ocean Surveyor ADCP (150kHz).

The currents were only partly measured sometimes during the leg. The ADCP could not determine the middle range of the water column currents for a still unknown reason. The ADCP also stopped receiving any information a few times due to ice under the ship blocking the signal.

2.2. Team 2

PI: David Barber (CEOS, University of Manitoba)
Participants: Mukesh Gupta (PhD Student, CEOS, University of Manitoba), Lauren Candlish (Masterôs Student, CEOS, University of Manitoba), Andrey Rubchenia (Professorôs Assistant, St. Petersburg State University)

2.2.1. Ice Dynamics

Participants: Mukesh Gupta and Lauren Candlish

Surface EM measurements

Objectives:

Ship-based ice-EM measurements were conducted to investigate the interactions between microwave signatures (both active and passive) and sea ice thermo-physical properties. The observed data will be used to calibrate sea-ice products from the satellite sensors and to evaluate the theoretical microwave emission/scattering models. This result will provide more advanced knowledge of how microwave signature reacts to the evolution of sea ice thermo-physical properties on small scales during the fall freeze-up period.

Instrumentation and methods:

The radiometers are dual polarized (vertical and horizontal) radiometers at 37 and 89 GHz with 6° beamwidth antennas (Radiometrics). The radiometers were mounted about 12 m above the sea surface on the portside of the ship. The radiometers were fixed at the incident angle of 55°. The SBR positioner did not work since the end of Leg 9A. A network camera (Cannon, VB-C10R) was mounted on a rail right beside the wheelhouse. The initial set-up for the camera was pan=0.00°, tilt=-25.00° and zoom=43.40° and was changed to tilt=-40.00° from Nov. 1. The pictures were taken every 10 seconds to 1 minutes depending on surface conditions. A hand-held digital camera was also used to record the visual surface condition. The data was acquired until August 1, 2008.

A C-band polarmetric (VV, VH, HV, HH) scattereometer system (PROSENSING) was deployed about 7.56 m above the sea surface (Figure 1). Whenever the ship was stationary, measurements from the ship were done from -30° to 30° in the azimuth, with the 0° reference at a perpendicular line to the ship side and from 20° to 60° in elevation at 5° increment. An infrared transducer (Everest, 4000L) was mounted on a rail in the shed for the C-band scattereometer system (Figure 1). The scatterometer positioner from University of Calgary was being used after June 26th onwards and data was acquired as per the plan.

Infrared Transducer back up was taken on weekly basis.

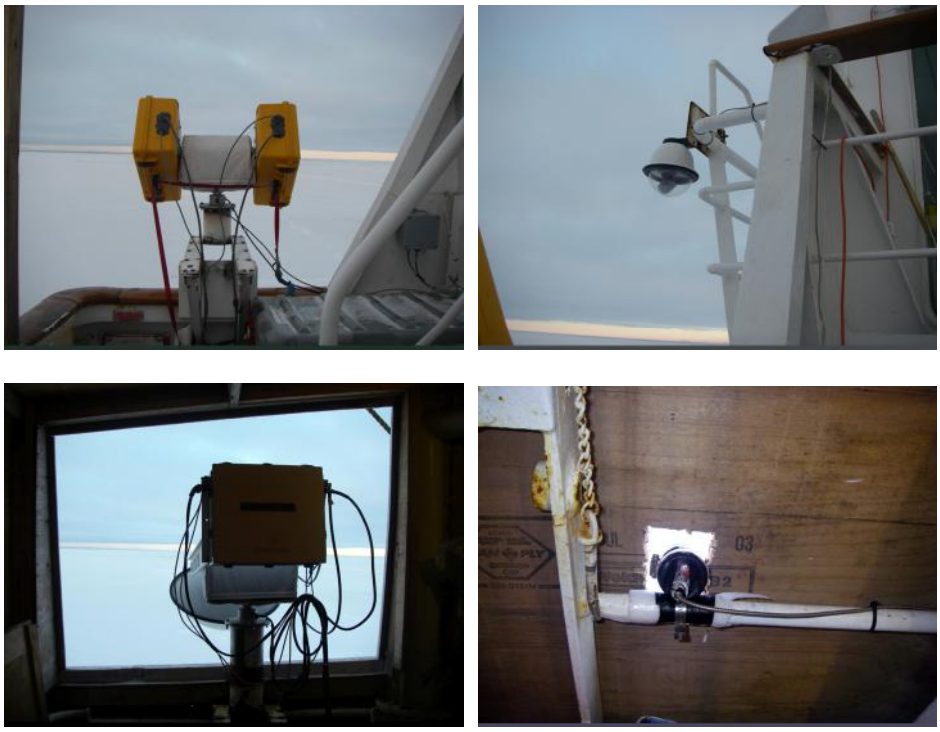

Fig. 1. Microwave radiometer system (top left), webcam (top right), scattereometer (bottom left) and infrared transducer (bottom right).

Meteorological Ocean Buoy (MOB)
The Meteorological Ocean Buoy (MOB) is comprised of a Data Well DWR-G4 buoy, modified to provide the additional functionality of a wind speed and direction sensor and an RF locating beacon. The Datawell DWG-4 buoy acquires and logs wave height data from a stabilized accelerometer, and wave direction data derived from GPS signals. To supplement this data, a number of additional parameters are collected and logged by the Metocean electronics (Metocean stack).

The Metocean stack includes an Ultrasonic Wind Sensor and a TCM2 compass that accurately measures the compass heading, buoy pitch and roll. Metocean stack also measures the battery voltage of the battery pack.

While the Datawell stack logs data into a flash card on the data logger on its stack, in order to store results from the Metocean Sensor stack, a second flash card is used with the Persistor CF-1 CompactFlash® datalogger module as part of the Metocean stack. Data from these flash cards can be saved on a hard drive independently and decoded using Metocean and datawell supplied decoding programs.

Once activated, the battery pack provides 25 days of continuous operation of the buoy. The Metocean stack samples various sensors connected to it once every 15 minutes and logs the results accordingly.

Deployment:
The buoy was deployed at every full station for minimum of 2 hours and maximum of 7 hours. It was deployed most of the time by line and kept 100 m away from the ship. Help from the crew in deployment and recuperation is highly appreciated.

Recuperation:
The buoy was recovered using zodiac and from the ship. The ship heading and the buoy bearing on ship DF was matched and the ship was sailed towards the buoy and a team with binoculars started finding the little yellow dot right in front of the ship. As soon as the buoy was spotted, zodiac was deployed to retrieve it or crew helped recovering it from the front deck using poles.

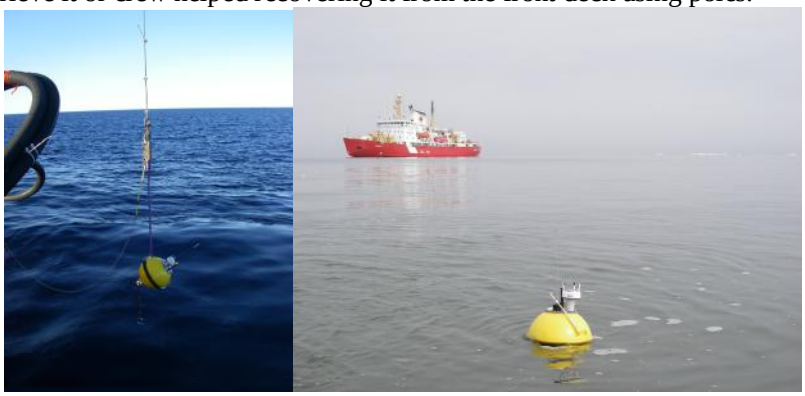

Fig. 2. Meteorological Ocean Buoy (MOB) deployment by line (left) and data acquisition (right).

Data acquired:

Table 1. MOB data acquisition dates.

Met Ocean Buoy s/no.	Date
E54021-02	July 23
	July 25
	July 26
	July 27
	July 30

On the performance of buoys:
The buoy worked very well during most of the deployments. The buoy was recuperated using zodiac with a hand held DF. High quality DF on ship was also used in parallel to track the buoy.

Vaisala wind sensors record data quite irregularly. Therefore, the surface wind data is not available for many stations. The reason behind the irregular functioning of wind sensor is still a mystery.

Laser Wave Slope (LAWAS)
Lawas was operated at every station when ship was at stop and sometimes during the motion.

Deployment:
For all open water stations, the Lawas was deployed on the foredeck on the beam (see picture).

Fig. 3. LAWAS deployment on foredeck.

The wind direction was noted at every deployment and picture of the wind tower was taken every time.

Table 2. LAWAS dates of data acquisition and station numbers.

Others
Other automated instruments viz. Laser Precipitation Gauge, Microwave Atmospheric Profiler, Webcam, Ceilometer and All Sky Camera acquired data as usual until August 1, 2008 and backed up frequently.

2.2.2. CTD measurements

Participant: Andrej Rubchenya.

Objectives
Description of thermohaline characteristics of water masses in Amundsen Gulf of Beaufort Sea.

Materials, methods and problems
Physical parameters of water were recorded using a rosette frame equipped with 24 bottles of 12L and the following sensors: CTD (SBE-911), temperature (SBE 3plus), pressure (SeaBird), conductivity (SBE 4C) and others (oxygen, PAR, fluorometer).

CTD was not working properly; there were problems with sensors and pump.

Field of measurements
16 stations with comparatively good data was made in Amundsen Gulf, and two ï on the slope in Beaufort Sea (Fig.1).

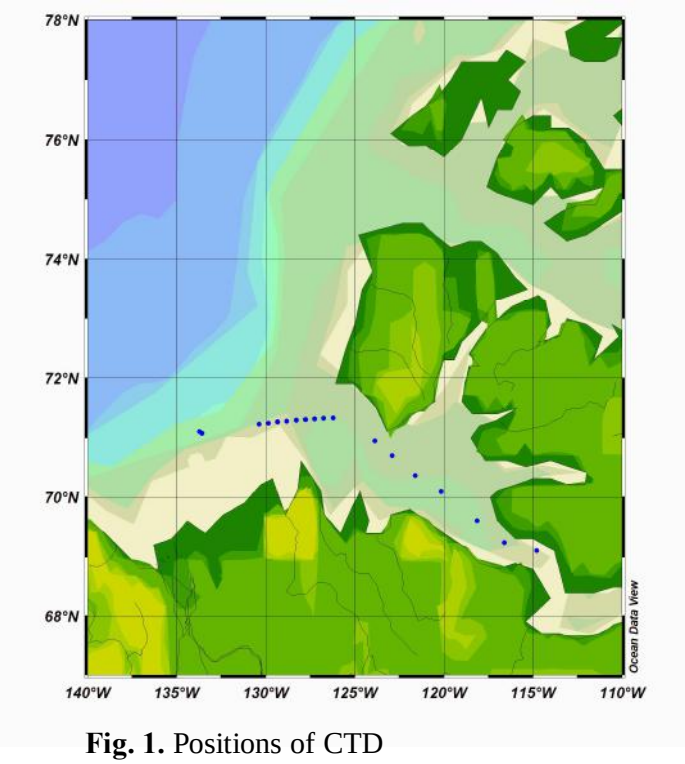

Fig. 1. Positions of CTD stations in Beaufort Sea.

Preliminary results

Only 18 stations (due to errors in others) were selected for primary analysis.
Using averaged data from 18 stations data (Jul, 19-Aug, 02) were prepared several sections and profiles.

Fig.2 illustrates surface temperature and salinity distribution.
On sections (Fig.3) we can clearly see freshing in upper layers.
Profiles of temperature and salinity, and T-S diagram presented on Fig.5.

2.3. Team 4

2.3.1. Zooplankton & Fish/ Acoustic/ Moored Sediment Traps

PI: Louis Fortier

Participants: Alexandre Forest (U. Laval), Makoto Sampei (U. Laval), Samuel Lauzon (U. Laval), and Louis Létourneau (U. Laval); with the precious help of Luc Michaud, Pascal Massot & Steve Gagné (ArcticNet central).

Introduction

The fragmented, thin, and often absent ice cover in the flaw lead allows solar radiation to reach the surface layer of the ocean where it triggers photosynthesis by microscopic algae. Team 4, Pelagic and Benthic Food Web, investigates how and to what extent microalgae growing in the flaw lead are consumed by the zooplankton and reach the benthos and how physical processes affect the abundance, physiology and community structure of zooplanktonic organisms. Our simple hypothesis is that, relative to adjacent ice-covered regions, enhanced algal production in the flaw lead translates into biological hot spots where higher zooplankton and benthos production prevail. We also investigate how the Arctic cod, a central species in the Arctic food web, uses the flaw lead for feeding, overwintering, reproduction, and as a nursery ground for their young stages (http://www.ipy-cfl.ca/page1/page1.html).

General objectives and summary

Our sampling program is derived from that of ArcticNet project 1.4 led by Dr. J.-É. Tremblay (U. Laval), ôMarine productivity and sustained exploitation of emerging fisheriesô, whose overarching goal is to assess the impact of sea-ice cover reduction and increasing sea temperatures on biological productivity, fisheries resources and marine mammal populations of the coastal Canadian Arctic. Since the beginning of the CFL field program last October, we focus on how physical processes moderate biogeochemical processes within the changing northern flaw lead ecosystem in the Amundsen Gulf - Banks Island area. The objective of the team 4 for the short three-week leg 10A was mainly to continue the work conducted during the previous leg in open water by deploying zooplankton nets from the front deck (double (horizontal), quadruple (vertical) 1-m^2 nets, Hydrobios and Rectangular Midwater Trawl). We concentrated our sampling efforts on pelagic secondary producers as well as on larval, and juvenile Arctic cod. An additional goal of our team during leg 10A was to recover and redeploy the automated instruments that record all year-long the vertical flux of biogenic matter and marine mammal distribution on the ArcticNet long-term marine observatories (i.e. moorings ï see leg 3 cruise report for details). Hence, our multidisciplinary ArcticNet-CFL team is strongly linked with Team 7 (Carbon Fluxes ï Tremblay) of the CFL program.

The primary objectives of our team during CFL-10A were:

1- To assess zooplankton / fish abundance and diversity by using various sampling devices.
2- To track zooplankton / fish biomass and distribution with the EK60 Echo sounder, and nets.
3- To turnover the automated sediment traps and hydrophones deployed on the moorings.

Our secondary field objectives were to collect and use zooplankton samples to:

1- Identify the sources and pathways of omega-3 in the Arctic marine food web (J. Michaud, E. Dewaily and L. Fortier, U. Laval). This project is linked to the CFL-URSUK program and ArcticNet theme 1.5, focusing on the importance of omega-3 fatty acids in the traditional diet of Inuit communities;
2- Assess the biomass and respiration rates of the zooplankton community by the Electron Transfer System (ETS) activity at specific stations (G. Darnis and L. Fortier);
3- Collect samples for stable isotope analysis of the food web structure and carbon fluxes mediated by zooplankton (i.e. calculation of gut evacuation rates [GER] and gut fluorescence content); this is a joint project between Teams 4 and 7 of CFL (A. Forest, L. Fortier, J-E. Tremblay, P. Wassmann);

4- Measure copepod *in-situ* egg production (EPR) and gonad maturation of *Calanus glacialis*, *C. hyperboreus* and *Metridia longa* (G. Darnis, L. Fortier);
5- Increase the size of arctic cod larval dataset (length-at-age) in order to validate an individual-based model designed to calculate growth and survival of this species (S. Thanassekos, L. Fortier).
6- To establish a conversion factor of backscatter intensity, from moored ADCP (acoustic Doppler current profiler), to dry weight and particulate carbon contents of zooplankton in water column. (M. Sampei, L. Fortier)

The short leg 10A (20-days) was fully devoted to open water sampling. Over the whole study area, sea ice has completely vanished when leg 10A began at mid-July. In total, 5 Full stations (i.e. mooring stations) and 4 Basic stations were visited for zooplankton & fish sampling. At a typical full station, the Hydrobios, Monster, Oblique tucker, and RMT (weather-dependent) were deployed whereas only the Monster and the Oblique tucker were used at a Basic station. Acoustics EK60 monitoring was done continuously during the cruise, but no fish schools were detected. A total number of 305 Arctic cod larvae were caught during leg 10, from which 221 were measured and preserved individually (see section III for details). On the 5 moorings, 6 sediment traps were recovered and 7 were redeployed. 5 hydrophones were recovered and 4 were redeployed. Weather conditions during leg 10A were not as good as in the previous leg and on-deck operations were often perturbed by strong winds (> 30 knots). Actually, science operations were cancelled for approximately 3 full days during leg 10A due to bad weather.

The Table 1 summarizes the sampling & science activities at each of the 9 stations visited during the short three-week leg 10A. The details of the operations are fully described in the following sections: Zooplankton & fish sampling; Mooring operations; Experiments and laboratory work; Acoustic monitoring.

Zooplankton & Fish Sampling
Overall, 32 sampling events occurred from which ~300 samples were preserved for taxonomy. Samples from the ódive towsô were used for laboratory experiments (as described in section V) or were frozen for further analyses at Laval University, Québec.

a) Hydrobios (Fig. 1a). Multi-depth plankton profiler equipped with nine 200 εm-mesh nets (opening 0.5 m^2) for depth specific sampling of the water column. The Hydrobios is also equipped with a CTD to record water column properties while collecting biological samples. Downward and upward winch speeds are 40 and 30 m/min respectively. For most casts, the net collection was preserved in formaldehyde for taxonomic analysis. However, the content of each net from some deployments was divided 50% for taxonomy (4% buffered formaldehyde), 25% for biomass estimates and 25% for ETS analysis. At mooring stations, a second Hydrobios cast was conducted to collect zooplankton samples to estimate zooplankton standing stocks in dry weight and particulate carbon from 0 to 100 m. These data will be used to establish a conversion factor of backscatter intensity, from moored ADCP (acoustic Doppler current profiler), to dry weight and particulate carbon contents of zooplankton in water column.

b) Monster net (Fig. 1b). Four 1-m^2 metal frames attached together, all rigged with a 1-m^2 200 εm mesh net, one with a TSK flow meter and one with a G.O. flow meter for abundance measurements, two with a 1-m^2 200 µm mesh net without a flow meter for "live" sampling, and an external 10 cm diameter 50 εm net. The gear is deployed vertically from 10 meters off the bottom to the surface. Downward and upward winch speeds are 40 and 30 m/min respectively.

c) Tucker net (Fig. 1c). Type gear rigged with two 1m^2-opening nets (500 µm mesh each), out-trigged with a 10 cm diameter net (50 εm mesh) and equipped with flowmeters (2 TSKôs) and a temperature-depth recorded (TDR). When towed, ship speed was 2-2.5 knots and winch speed down was around 30 m/min and around 20m/min on the way up. This gear was mainly use to catch fish larvae and to provide water column zooplankton samples from the upper 100 m layer. One of the 500 µm mesh net was preserved in 4% buffered formaldehyde for

taxonomy and the other 500 µm mesh met was frozen for further analyses.

d) Rectangular Midwater Trawl (RMT, Fig. 1d**).** Trawl with an opening of 9 m^2 fitted with a 1600 εm mesh-net. When towed, ship speed was typically 2-3 knots; and winch speed down was 30 m/min and around 20 m/min on the way up. This net, only deployed at full stations when weather conditions allowed, was used to catch larval and fish. Collected zooplankton was frozen for further studies.

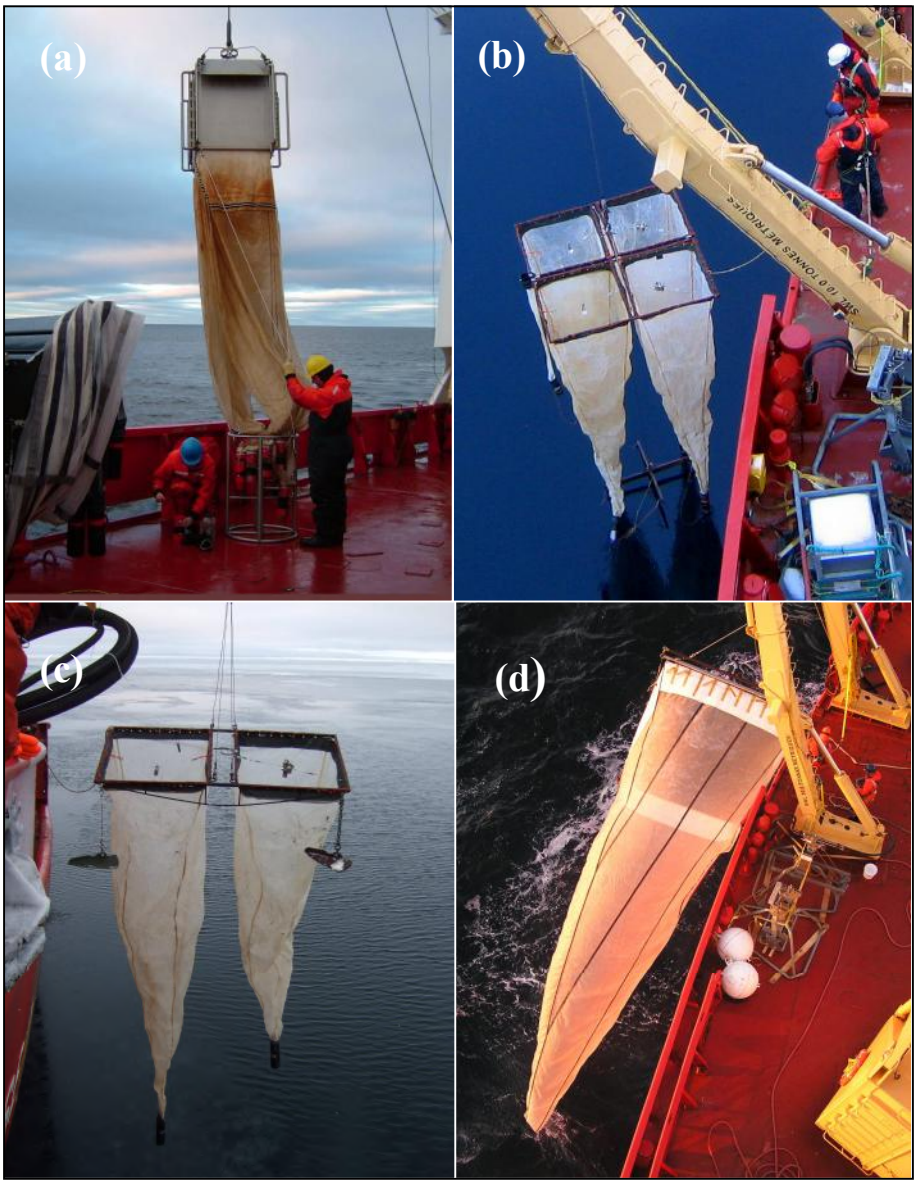

Figure 2: Standard length of Arctic cod larvae caught during the CFL program since May 1st, 2008 (legs 8, 9 and 10)

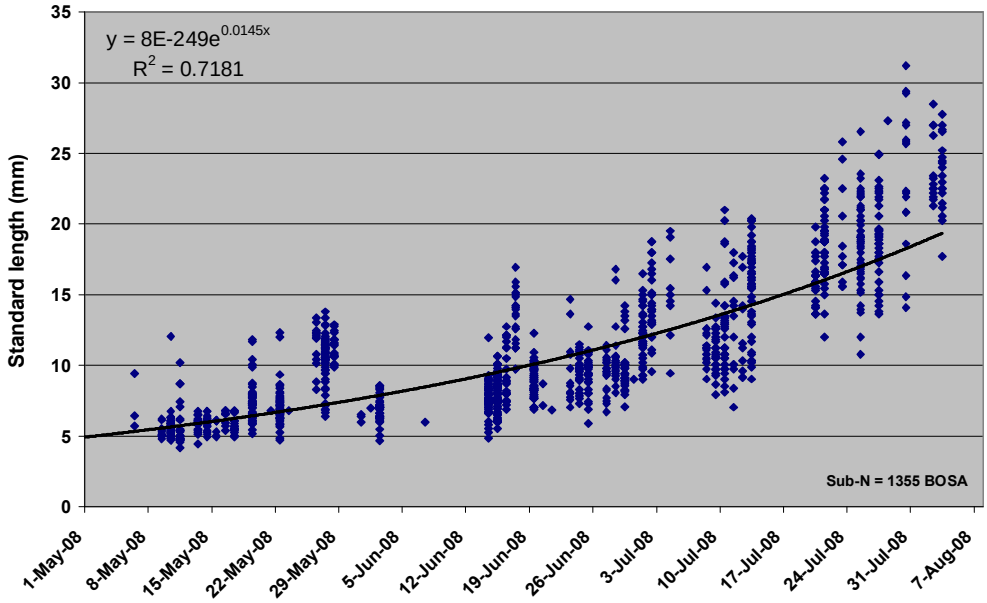

Mooring operations

As part of CFL/ArcticNet, nine long-term sediment traps have been deployed at ca. 100 m on CA05 and CA08, at ca. 100 m and 200 m on CA04 and CA16, and at ca. 100m, 200m and 480 m (50 m above the bottom) on CA18 from October 2007 to late July 2008. Six sediment traps (at CA04, 05, 08 and 16) were successfully recovered on the Canadian Coast Guard ice-breaker *Amundsen* during CFL Leg 10A. Seven sediment traps have been re-deployed at CA04, 05, 16 and 18 during this cruise. These traps will be recovered in September 2009 (on ArcticNet cruise). The samples from sediment traps will be processed for chemical analysis (DW, POC, PON, Si and Al) and microscopic observations (counting on phytoplankton, zooplankton swimmers and fecal pellets). This will allow us to analyze the seasonal pattern of biogenic matter sinking to the seafloor, and to quantify the vertical export pathway of particulate organic carbon. For future sediment traps deployments, we recommend that our sediment trap, TECHNICAP PPS3/3 24-cups (Figure 3a) should be equipped with a stronger joint between the vertical steel bar and the glass-fiber chassis. By example, it could be good to put ropes around the chassis at top- and bottom-end and/or to build steel rings around the trap.

On the moorings, we also recovered five passive hydrophones (Figure 3b), while four hydrophones were redeployed (at CA04, 05 16, 18). Later analyses of the recovered data will allow our team to track marine mammal distribution in the CFL area during 2007-2008.

Experiments and laboratory work
Chosen samples from the Monster Net and Hydrobios were used for further analyses and laboratory experiments. Samples for lipid and stable isotopes analyses were placed in cryovials and stored at -80ęC. Other samples were preserved as a *bulk* at -80ęC for later gut fluorescence measurements. All these samples will be sorted and analysed at Laval University. Some experiment took place directly on board:

1) **Egg production rate experiments (EPR)**
   Copepod *in-situ* egg production rate (EPR) were monitored by incubating the females of three species (*Calanus hyperboreus*, *C. glacialis* and *Metridia longa*) at 0°C, a temperature similar to that they experience in their environment. The results from the experiments conducted during leg 10 showed that the egg production season is over for all these species. Poor abundance of females *C. glacialis* limited our capacity to sort enough organisms for the EPR experiments.
2) **Biomass and Transfer System (ETS) activity**
   Samples were sorted for biomass and ETS activity assays at 3 Hydrobios stations (Table 1). At these stations, each Hydrobios net was subdivided: 50% for taxonomy (i.e. preserved in formol), 25% for population biomass estimates and 25% for ETS activity measurements. For biomass estimates, the sub-sample (i.e. 25% of total sample) was fractionated with sieves in > 1000 µm and < 1000 µm size classes; these fractions were preserved at -0ęC. Sub-samples for zooplankton population ETS activity assays (i.e. 25% of the total sample) were also sieved through the same two size fractions. Samples were incubated at 40ęC. ETS experiments were also performed on individual copepods of *Calanus glacialis*, *C. hyperboreus* and *Metridia longa*.
3) **Respiration experiments**
   To derive respiration from the activity of the Electron Transfer System (ETS), a ratio of respiration on ETS activity is required. Thus, 3 incubations were carried out to measure oxygen consumption of zooplankton and selected copepods species in sealed chambers.
4) **Gut evacuation rate experiments**
   To calculate ingestion rates of mesozooplankton, gut evacuation rates and gut fluorescence measurements are needed. Thus, at each station, a live tow from the Monster Net was quickly incubated at 0°C for 60 minutes in a 11-L incubation chamber. About 500 mL of mesozooplankton were filtered on a 200µ mesh at T=0, 5, 15, 30, 45 and 60 minutes, and were rapidly frozen at -80°C. Later chlorophyll extraction and fluorescence biomass measurement from frozen mesozooplankton at Laval University will allow us to calculate the phytoplankton ingestion rates of the diverse zooplankton species.

Acoustic monitoring
The Simrad EK-60 Echosounder of the Amundsen allows our group to continuously monitor the spatial and vertical distribution of zooplankton and fish, the later mostly represented by Arctic cod (*Boreogadus saida*). The hull-mounted transducers are in operation 24h a day and will provide a mapping of where the fishes are within the region of interest over a yearly cycle.

2.4. Team 6

2.4.1. Surface Meteorology and Flux Project

PI: Tim Papakyriakou (University of Manitoba)
Participant: Silvia Gremes-Cordero (RSMAS, U of Miami, USA)

Introduction
The surface meteorology and flux program (CFL Team 6) is designed to record basic meteorological conditions and to study exchanges of momentum, heat and mass across the atmosphere-sea ice-ocean

interface. The main value of this program to the overarching objectives of Team 6 is the direct measurement of CO_2 fluxes.

Turbulent fluxes of CO_2 are measured by the eddy covariance technique, which is dependent only on atmospheric measurements. Although measurement of these fluxes is extremely useful information, it is essentially meaningless without an understanding of the processes (physical, biological and chemical) that drive gas exchange. In an open-ocean situation this context is largely provided by measurement of sea-surface pCO_2, but the situation becomes much more complex when a sea ice cover is included in the equation.

This section of the CFL Team 6 cruise report reviews the atmospheric and sea surface pCO_2 measurements that were made during Leg 9. Other sections of the annual report will deal with the sea ice measurements that were made in support of the CO_2 flux measurements.

Amundsen Micrometeorology and Eddy Covariance Flux Tower

Methods

The micrometeorological tower located on the front deck of the Amundsen (Figure 1) provided continuous monitoring of meteorological variables and eddy covariance parameters. The tower consists of slow response sensors that record bulk meteorological conditions (air temperature, humidity, wind speed/direction, surface temperature) and fast response sensors that record the eddy covariance parameters (CO_2/H_2O concentration, 3D wind velocity, 3D ship motion, air temperature) (Table 1). In addition, radiation sensors (Figure 1, Table 1) were installed on the roof of the wheelhouse to provide information on incoming longwave, shortwave and photosynethetically active radiation. All data was logged to Campbell Scientific dataloggers; a model CR5000 logger was used for the eddy covariance data, a CR1000 logger for the slow response met data, and a CR23X for the radiation data. All loggers were synchronized to UTC time using the shipôs GPS system as a reference.

The eddy covariance system on the tower makes use of two separate gas analyzers and a single 3D sonic anemometer. The dual gas analyzers system allows us to make use of both closed path and open path eddy covariance systems. The open path gas analyzer has the benefit of making measurements concurrently with the sonic anemometer, but the closed path gas analyzer is not as easily disturbed by adverse weather conditions.

In order to make sure that the two systems are comparable, careful calibrations were performed on both instruments. The closed path system is based on a LI-7000 gas analyzer which employs two optical cells, one of which was used to monitor the drift of the instrument by constantly passing a stream of ultra-high purity N_2. In addition, the sample cell of the instrument was calibrated daily using the ultra-high purity N_2 to zero the CO_2 and H_2O measurements, and a reference gas of known CO_2 to span the instrument. Occasionally, a span calibration of the H_2O sensor was performed using a dew point generator (model LI-610).

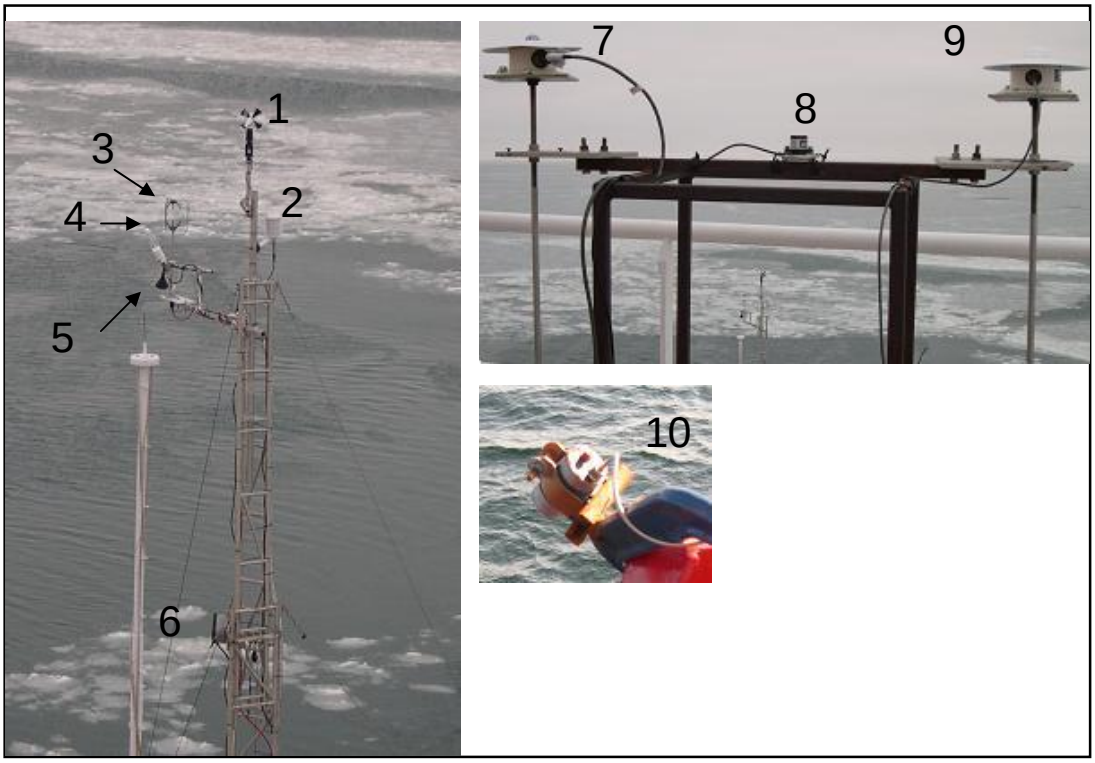

Figure 1: Meteorology and flux program instrument setup. See Table 1 for description of instruments based on the numbers. Note that on Nov. 18 the Motion Pak (6) was moved to the rear face of the tower to facilitate easier motion correction.

Table 1: Description of instruments shown in Fig. 1.

Notes
The meteorological tower ran consistently for the duration of the leg (June 5 ï July 16) with the exception of brief periods when the tower was taken down for maintenance. However, for significant periods of time during the leg certain sensors were inoperable due to atmospheric conditions. The most common problem encountered during this leg was riming due to the cold, moist conditions. The extent of data lost due to atmospheric conditions cannot be estimated at this time, and will only be known once post processing is complete.

On-track pCO2 System

Methods
A custom-built pCO_2 system was utilized on this leg to measure dissolved CO_2 at the sea surface in near real time. The system (Figure 2) is located in the engine room of the Amundsen, and draws sample water from the shipôs clean water intake. The water is passed into a sealed container through a shower head, maintaining a constant headspace. This set up allows the air in the headspace to come into equilibrium with the CO_2 concentration of the seawater, and the air is then cycled from the container into a LI-7000 gas analyzer in a closed loop. Thermocouples are used to measure water temperature immediately before entering the equilibration chamber, and to measure the temperature of the air in the chamber. All data is logged to a Campbell Scientific CR1000 datalogger.

The LI-7000 gas analyzer was calibrated daily using ultra-high purity N_2 as a zero gas, and a gas with known CO_2 concentration as a span gas. Spanning of the H_2O sensor was not necessary because a desiccant column removes H_2O from the air stream before passing into the sample cell. As with the closed path system, a stream of N_2 is constantly cycled through the reference cell of the LI-7000 to monitor and correct for drift of the instrument.

Figure 2: The on-track pCO_2 system located in the engine room of the Amundsen. The equilibration chamber is the clear cylinder (left bottom) and the gas analyzer is the box with the digital display.

Notes
The on-track pCO_2 system was active for the duration of the leg, with some minor interruptions for maintenance. Major interruptions in data collection were experienced when the ship was breaking ice, which either reduced the flow of water into the equilibration tank, or completely blocked it. In the case of blocked flow, the data is lost, but tests will have to be conducted to determine if data obtained with low water flow is useful. Preliminary results suggest that the pCO_2 values calculated from the DIC samples match very well with the equilibrator values.

2.4.2. Laser Wave System (LAWAS) Project

Participant: Silvia Gremes-Cordero (RSMAS, U of Miami, USA)

The University of Miami LAWAS consists of 4 Riegl LD90-3 laser altimeters mounted in a square array of 0.3m diameter. LAWAS is mounted on a boom near the bow on the port side (see Fig. 3). A Systron Donner MotionPak is mounted at the center of the array to measure all six components of motion of the laser array.

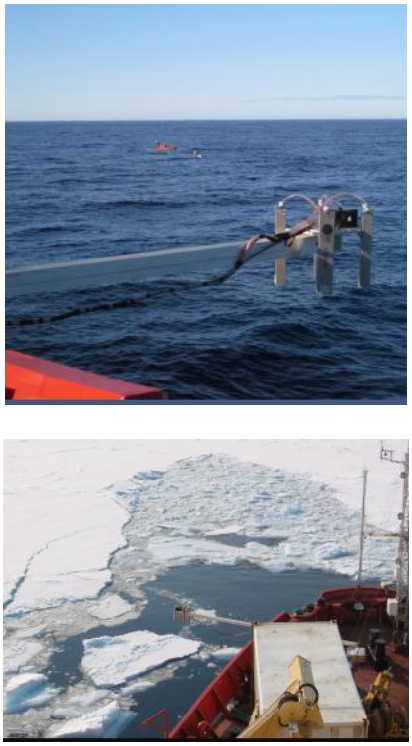

Fig. 3 Photographs showing LAWAS position near bow of Amundsen

The LAWAS system is designed to measure time series of wave slope in two directions, from which rms slope of the sea surface can be calculated. Of particular interest are measurements coincident with Quiksat overpasses. Typically eight overpasses occur each day, between 01 ï 13 UTC. The project objective is to relate CO2 gas transfer to Quikscat derived backscatter measurements. LAWAS deployments took place on July 18th, 19th,21th , 22nd, 26th ,27th , 29th , 31st, and August 1st, during different weather condition, including 30 kn winds and rain.

The data was obtained at a ship speed between 2 and 5 kn, depending on the surface conditions, but also at full ship speed and at 7 knots (maximum ship speed before bow-generated wake appears). During the dedicated time, the wind direction was 0 degrees relative, or with a maximum relative angle of 30 degrees, in order to allow a comparison with the flux tower data.

2.4.3. Carbon monoxide

PI: H. Xie
Participant: Cyril Aubry

Objectives:

1. To determine the spatiotemporal distributions of carbon monoxide (CO) in various types of sea ice.
2. To determine the concurrent distributions of colored dissolved organic matter (CDOM), dissolved organic carbon (DOC) and salinity.
3. To assess the relationships between the distribution of CO and the distributions of CDOM, DOC, and salinity.
4. To model the photoproduction of CO in sea ice.
5. To determine the seasonal evolution of the microbial CO uptake kinetics.

Activities:

Six land-fast ice sites were sampled during Leg 9 (Table 1). Each ice core was cut into 8-9 sections and sub-sampled into 200-ml glass syringes. Ice in the syringe was melted in a water bath. CO in the ice was quantified with a manual headspace method aboard the ship. The melt water was 0.2-µm filtered and will be brought to a land-based laboratory at Rimouski for CDOM and DOC measurements.

Three to six different Melt ponds were sampled for few days, in Darnley Bay and Franklin Bay sites, for CO concentration and salinity. When possible, daily variation in concentration was followed by sampling in the morning, afternoon and evening for the same melt ponds.

One brine sample and one melt pond water were also collected from Franklin Bay land-fast ice site (Stn F8). These samples will be used to determine the efficiency spectra of CO photochemical production in the ice and the melt ponds. The efficiency spectra, in conjunction with sea ice optical data from the sea ice physics group, will be used to model CO photoproduction rates in sea ice and in melt ponds.

Time-course incubations of microbial CO uptake were conducted at nineteen stations (Table 1) to elucidate how CO uptake kinetics changes with CO concentration and with season. For some stations, samples were taken on 4 depths to increase the depth resolution of microbial CO uptake.

Data collected aboard the ship (see Table 1)

Table 1. Data collected aboard the ship

Stn	Date	Sample (ice/water)	Number of depths/time sampled	CO	S	Microbial CO uptake

2.5. Team 7

2.5.1. Carbon & nutrient fluxes

PI: Jean-Éric Tremblay (Department of Biology, Laval University)
Participants: Jonathan Gagnon, Mariane Berrouard & Marjolaine Blais (Department of Biology, Laval University)

Rationale. The Arctic climate displays high inter-annual variability and decadal oscillations that modulate growth conditions for marine primary producers. Much deeper perturbations recently became evident in conjunction with globally rising CO_2 levels and temperatures (ACIA 2004; Comiso 2003). The thickness and extent of Arctic sea-ice decrease rapidly (Johannessen et al. 1999; Rothrock et al. 1999) and the ice-free season is extending both in the Arctic (Laxon et al. 2003) and subarctic (Stabeno & Overland 2001). Models predict further reductions in ice cover (ACIA 2004). These changes entail a greater penetration of light into surface waters, which is expected to bolster phytoplankton production (Rysgaard et al. 1999), food web productivity and CO_2 drawdown by the ocean. At present, phytoplankton production varies by two orders of magnitude across the Canadian Arctic, but the forcing mechanisms are poorly understood and quantified. In the Canadian Archipelago, the productivity of phytoplankton is likely to be limited by light or the supply of allochtonous nitrogen, depending on ice conditions. The supply of allochtonous nitrogen is influenced by climate-driven processes, mainly the large-scale circulation, river discharge, upwelling and regional mixing processes. Over most of the western Arctic, and especially the Beaufort Sea, the concentrations of inorganic nitrogen (i.e. nitrate, nitrite and ammonia) at surface remain low throughout the year and the phytoplankton possibly depend on local recycling and the dissolved organic nitrogen (DON; e.g. urea, amino acids and primary amines) supplied by rivers. A large portion of the phytoplankton biomass is typically located within subsurface chlorophyll maxima (SCM). SCM productivity is possibly in balance with the episodic supply of nitrate across the halocline and/or the supply of ammonium and nitrate by local recycling and nitrification, respectively. Despite the importance of SCM for the food web and CO_2 fluxes, little is known about their structure, turnover and susceptibility to environmental variability and change.

Objectives. The main goals of our team for leg 10a of CFL were to **(1)** establish the horizontal and vertical distributions of phytoplankton nutrients and the influence of different processes (e.g. mixing, upwelling and biological processes) on these distributions, **(2)** characterize the detailed vertical structure of chlorophyll-*a* with respect to irradiance, nutrient supply and physical structure, **(3)** experimentally assess causal relationships between the assimilation of different nitrogen sources by phytoplankton and the availability of light **(4)** determine the utilisation of different sources of inorganic and organic nitrogen by phytoplankton and bacteria, **(5)** determinate the rates of nitrification and **(6)** the regeneration of ammonium at SCM. Ancillary objectives were to calibrate the *SeaPoint* fluorometer and *ISUS* nitrate probe attached to the Rosette.

Methods. Samples for inorganic nutrients (ammonium, nitrite, nitrate, orthophosphate and orthosilicic acid) were taken at all rosette stations (see Table 1) to establish detailed vertical profiles (see Fig. 1 for vertical sampling resolution). Additional samples for dissolved organic nitrogen (DON) and urea were taken at stations where incubations were performed. Ammonium was determined immediately after collection using modifications of the manual fluorometric method (e.g. Holmes et al. 1999). Urea samples were stored frozen and DON samples were preserved with acid and stored in the dark at 4°C for post-cruise determination. The concentrations of nitrate, nitrite, orthophosphate and orthosilicic acid were determined on fresh samples using an Autoanalyzer 3 (Bran+Luebbe) with colorimetric methods adapted from Grasshof (1999).

Samples for the natural abundance of ^{15}N and ^{13}C in particulate organic matter were taken at 5 m and in the chlorophyll maximum at stations where incubations were performed (Table 1). Volumes ranging from 12 to 20 liters were filtered onto 47 mm pre-combusted GF/F filters with a peristaltic pump and the filters were desiccated at 60°C in a drying oven. These data will be used for nitrogen uptake calculations and to assess the nitrogen status of phytoplankton communities.

The relationship between light and the uptake of C and N by phytoplankton from the surface was assessed using dual labelling with stable isotopes of C and N in four light-gradient modules (10 light intensities). Temperature was maintained at *in situ* levels with a chilling circulator. Ten samples for each nitrogen source were spiked (10 with ^{15}N-nitrate and ^{13}C-bicarbonate, 10 with ^{15}N-ammonium and ^{13}C-bicarbonate, 10 with $^{13}C/^{15}N$-urea and 10 with $^{13}C/^{15}N$-glycine). Incubations were terminated by filtration onto 24-mm pre-combusted glass fiber filters. All filters were desiccated at 60°C and stored dry for post-cruise determination of isotopic enrichment and the measurement of both particulate organic carbon and nitrogen.

The rate of assimilation of the same four nitrogen sources by phytoplankton and bacteria from surface and chlorophyll maximum depth were also assessed with natural irradiance, using on-deck incubators covered with filters to simulate natural light conditions at those depths. Incubations were terminated by filtrations onto 0.8µm and 0,2µm silver filter. The filtrates of the samples incubated with ^{15}N-ammonium and ^{13}C-bicarbonate were acidified and frozen for post-cruise analysis of regeneration of ammonium using the method of Holmes (1998) and for measurement of the nitrification rate by the extraction of ^{15}N-nitrite with the method of Olsen (1981).

Presence of dinitrogen fixation in surface water was verified by using the method described by Montoya *et al.* (1996) with on-deck incubators. Incubations were terminated by filtration onto 3 µm and 0,2µm silver filter. All filters were desiccated at 60°C and stored dry for post-cruise determination of isotopic enrichment and the measurement of both particulate organic carbon and nitrogen.

The effects of incubation treatments (variable nutrient additions, temperature and light conditions) on the photosynthetic characteristics of phytoplankton were assessed by Pulse Amplitude Modulated fluorometry (PAM; Heinz-Walz). Calibration of the Rosette fluorometer was achieved by comparing the instrumentôs output with extracted chlorophyll *a* and PAM data. The Phytoflash system was powered by a CTD (SBE-19) and deployed in self-contained mode from the front deck.

2.5.2. Marine Photochemistry

Participants: Cédric G. Fichot, Simon Bélanger, Ron Benner

Introduction
Major uncertainties currently exist within global budgets of carbon, nitrogen, phosphorous and sulfur (Berner and Lasaga, 1989; Sarmiento, 1993; IPCC, 2001). Attempts at filling gaps in these budgets have led scientists to recognize the potential role of marine photochemistry in global biogeochemical cycling. In its broadest sense, marine photochemistry refers to the chemical processes that result from the interaction of solar radiation with all seawater constituents. However, since most photochemically-efficient solar radiation (ultraviolet and blue region of the solar spectrum, 280-500 nm) in the ocean is scavenged by chromophoric dissolved organic matter (CDOM), most marine photochemical studies are concerned with the effects of solar radiation on the dissolved constituents of seawater.

Studies over the past four decades have demonstrated that marine photochemistry is involved in a variety of chemical reactions of significance to numerous marine, atmospheric and climate-related processes (Zepp et al., 1998; Mopper and Kieber, 2000; Zepp et al., 2007). Through absorption of solar radiation, the ubiquitous CDOM undergoes photochemical reactions, serving as the major precursor for the creation of a variety of short-lived radicals and stable photoproducts. Photoproducts important to carbon cycles include dissolved inorganic carbon (DIC) carbon monoxide (CO) and a variety of low molecular weight (LMW) biologically labile carbon compounds (Mopper and Kieber, 2001). Among other processes, marine photochemistry also acts as: a direct sink for dissolved organic matter (DOM) ; a source of volatile sulfur compounds (COS, CS_2) (Xie et al., 1998; Uher and Andreae, 1997) and methyl iodide (CH_3I) (Moore and Zafiriou, 1994) ; a potentially significant and indirect sink for dimethyl sulfide (DMS) in the ocean (Brimblecombe and Shooter, 1986; Kieber et al., 1996). In light of these recent findings, the need to quantify the role of marine photochemical processes in global biogeochemical cycles is being increasingly recognized by the scientific community.

As a result of their dependence on incident solar radiation, photochemical processes in the Arctic are extremely seasonal with maximum rates in summertime. Meanwhile, the continuous shrinking of the summer ice cap contributes to a larger fraction of the ocean becoming exposed to solar radiation. In addition, a recent increase in incident UV radiation and the release of large amounts of terrestrial DOM from the melting of the permafrost are also expected to make photochemical fluxes increasingly significant in the forthcoming years.

Bélanger et al. (2006) provided the first estimate of photochemical remineralization of terrestrial DOM in the Arctic using remote sensing. Although novel, their approach is severely hindered by our lack of knowledge about the photoreactivity of the photochemical precursor (CDOM).

Objective

Our objective is to gain a better understanding of how the photoreactivity of DOM relates to its composition in an attempt to provide a better quantitative assessment (using remote sensing) of the role of marine photochemistry in biogeochemical cycling of carbon and nitrogen in the Arctic. In particular, we investigate the role played by DOM components of terrestrial origin as they are suspected to play a disproportionately large role in photochemical processes.

Methods

Optical measurements for algorithm development and validation (Optics):

1) Hyperspectral remote-sensing reflectance, $R_{rs}(\lambda)$ with λ = 350 - 700 nm, using a Satlantic® HyperSAS (belonging to Dave Barber). Measurements were done onboard the Amundsen at the bow under clear-sky conditions only and around 2 P.M (local time) to maximize the likelihood of match-up with remotely sensed reflectances (SeaWiFS and MODIS). See figure 1 for illustration.
2) Simultaneous sampling of surface seawater (0 m) for measurements of absorption coefficients of CDOM, $a_g(\lambda)$, and particles, $a_p(\lambda)$. Filtrations were done onboard the Amundsen and spectrophotometry will be done in the lab at the Université du Québec à Rimouski.

Water sampling for determination of DOM composition (DOM composition):

1) A WetLABS ECO CDOM fluorometer (ex/em 370/460 nm) plugged into the CTD/rosette was deployed during some of the CTD casts. When deployed, the CDOM fluorescence profiles exhibited minima in the surface mixed layer and maxima somewhere in the 60-120 m depth range. See figure 2 for illustration.
2) About 100 mL of filtered seawater (GF/F, 0.7 mm) was collected for measurements of DOC, DON, CDOM absorption coefficient spectra, $a_g(\lambda)$, amino acids and possibly $d^{13}C$. For each station sampled, samples at 2 or 3 depths were obtained (usually surface (5 m), mid-water column or CDOM fluorescence maximum and near the bottom). Samples are kept frozen (- 20 ^{o}C) and will be analyzed by Cedric Fichot in Dr R. Benner's lab at the University of South Carolina.
3) Lignin extraction for lignin oxidation product analysis was done based following the method of Louchouarn et al. (2000). About 10 L of 0.2 mm-filtered acidified (pH ~ 2.5) seawater (from the same Niskin bottle as for item 2) was used for lignin extraction on the C18 Varian cartridges. After extraction, cartridges are kept at + 4 ^{o}C and will be processed by Cedric Fichot in Dr R. Benner's lab at the University of South Carolina for analysis of lignin oxidation product analysis. See figure 3 for illustration.

Water sampling for photochemical experiments (Photochemistry)

1) Either 300 mL or 1.2 L of 0.2 mm-filtered seawater were collected from the same Niskin bottles as the DOM Composition samples. Samples are kept at + 4 ^{o}C and will be used by Cedric Fichot in Dr R. Benner's lab at the University of South Carolina in a series of photochemical experiments aimed at determining the photoreactivity of the DOM sampled.

2.5.3. Dissolved Inorganic Carbon System

PI: Helmuth Thomas
Participant: Stephanie Moore; Department of Oceanography, Dalhousie University, Halifax, NS, Canada; moore@phys.ocean.dal.ca

The oceanôs exchange of carbon dioxide with the atmosphere is governed by the biogeochemical cycling of carbon and physical processes throughout the water column, which determine the concentration of dissolved inorganic carbon in the surface waters. Of the seven relevant carbon system parameters, a minimum of two are needed to calculate the others and fully describe the inorganic carbon chemistry, over-determination of the system being beneficial. During CFL Leg 10a, roughly 110 samples were analyzed for dissolved inorganic carbon (DIC) and total alkalinity (TA), yielding two of the relevant parameters. Due to project priorities, problems with the CTD, and bad weather less than half the expected sampling was done, accounting for the low number of analyzed samples.

Water samples were collected at full, basic and mooring stations in parallel with the nutrients rosettes. DIC and TA were sampled using 500 mL glass bottles which were rinsed and filled using a plastic tube. DIC samples were the first to be taken from the Niskin bottles. These samples were either

analyzed immediately following sampling, or spiked with $HgCl_2$ and stored in the dark at 4°C to await analysis.

Water was sampled from the entire water column from the bottom water up to 5 meters depth. At station 408, the only station for which time and weather permitted, surface water was collected with the use of the zodiac. This water was collected using a Niskin bottle. The salinity of the sample was measured with a salinometer.

DIC and TA were analyzed on board using a VINDTA 3C (Versatile Instrument for the Determination of Titration Alkalinity) by Marianda. Total alkalinity was determined by titrating a volumetrically accurate sub-sample of seawater using HCl as a titrant. In the case of dissolved inorganic carbon, a volumetrically determined sub-sample of seawater is acidified with 8.5% H_3PO_4 to convert all inorganic carbon into gaseous CO_2. The CO_2 is then stripped out of the sample using ultra-pure N_2 gas, followed by transfer into the titration cell where total inorganic carbon is then detected using the coulometric method (Johnson et al., 1993).

Surface water samples were also collected at four stations near the MacKenzie River delta. Since the Niskin broke on the way to the river, the samples were collected by submerging the 500 mL glass bottles. These samples were subsequently analyzed for DIC and TA. This was of particular interest, since TA can be used as a fresh water tracer. Measurements of alkalinity from this freshwater source should allow us to distinguish between freshwater input from sea ice melt and freshwater input from the MacKenzie river to the Arctic Ocean in the CFL sampling region.

2.5.4. Barium

PI: Helmuth Thomas
Participant: Stephanie Moore; Department of Oceanography, Dalhousie University, Halifax, NS, Canada; moore@phys.ocean.dal.ca

In the Canadian Arctic, barium (Ba) is mainly released from the North American continent and can therefore be used as a tracer for terrestrial freshwater input. Together with ^{18}O, a tracer for freshwater input from precipitation and ice melt, all freshwater sources to the Arctic can be quantified.

Throughout Leg 10a, samples for barium were taken from the rosette parallel to samples for ^{18}O, at approximate depths 5, 10, 20, 50, 70, 100, 200 and 400 m. Small plastic bottles (15 ml volume) were

rinsed three times, then filled and spiked with 15 µl concentrated HCl. Sample bottles were then sealed with parafilm and kept for later analysis using isotope dilution mass spectrometry.

2.5.5. Sediment traps

PI: Christine Michel, Freshwater Institute Winnipeg (DFO)
Participant: Amélie Sallon, University of Québec of Rimouski (UQAR)

Sediment traps have been used to estimate the sinking flux of organic material in the ocean and to assess the composition of that flux. There are two pathways to describe organic carbon in the water column. 1) Phytoplankton carbon can be transferred to the higher trophic level by zooplankton grazing. Part of this carbon can be used by other organisms including fish, mammals and bird, while another part may be exported at deeper depth in the form of fecal pellets (feces). This pathway favors transfer to the pelagic ecosystem. 2) On the other hand, phytoplankton carbon that is not used can be directly exported through sedimentation of intact cells. This pathway leads to food input to the benthic (sea floor) community.

Objectives
This study investigates the biogeochemical cycling of carbon and other organic constituents through the use of short-term particle interceptor traps. The general objective of this study is to characterize the sinking export of carbon and organic material from the euphotic zone (magnitude and composition of the sinking fluxes and material), and the transformation of material during its sinking to depth. This research aims at understanding how climate-related changes in the distribution, timing, magnitude and type of primary production may affect the fluxes of material to the benthic and pelagic food webs.

Methods
During CFL program (17^{th} of July to 5^{th} of August 2007), we deployed the traps at five stations (5 mooring stations) throughout the Canadian High Arctic. The traps were PVC cylinders with an internal diameter of 10 cm and a height/diameter ratio of 7. Before each deployment, seawater collected at 150-200m deep at a previous station was filtered through 0.22 µm filter membranes. The traps were filled with the filtered seawater to create a dense layer. A series of five PVC cylinders were installed on a line at each sampling depth (50m, 100m, and 150m) in order to collect enough material to perform subsequent analyses. At the surface, the trap line was attached to a positioning system (ARGOS and radio beacon) and a series of small floats (Viny floats) to minimize vertical motion. The traps were deployed for a period of 12-24 hours. Upon recovery, the traps were placed in a dark cold room for 8 h. After allowing the sediment to settle, the supernatant was removed and the bottom volume (ca. 1000ml) of the traps was kept for analysis. Samples were analyzed for particulate organic carbon and nitrogen (POC/PON), dissolved organic carbon (DOC) and nitrogen (DON), stable isotopes (Isotopes), biogenic silica (BioSi), total chlorophyll *a* and phaeopigments (total chl*a*), exopolymeric substances (EPS) phytoplankton composition and abundance (Cells), fecal pellet abundance (FP), bacteria (FC) and thorium (Th) (Table 1).

Another aspect of this project is to evaluate the spatial and vertical distribution of dissolved organic carbon and nitrogen in Arctic marine waters, as these constituents play important roles in the cycling of organic material on the shelves. Water column samples were taken at all basic and full stations throughout the Canadian High Arctic for a total of 6 stations.

2.5.6. Marine Microbiology Group

Participants: Mary Thaler (Universite Laval), Cristina Romera (Institut de ciencies del mar)

Objectives
Our team collected samples and data for three laboratories: Connie Lovejoy, Roxanne Marangar and Carlos Pedros-Alio. Our work addressed different aspects of microbial diversity and processes in the Amundsen Gulf at this time of year, including both eukaryotic and prokaryotic groups.

Sampling and data collection
DNA and RNA
DNA and RNA were sampled together from the same casts and depths from which the nitrogen team (Mariane and Marjolaine) drew their samples, typically the surface and the chlorophyll maximum. Three times during the leg, the full water column was sampled including bottom, O_2 minimum and/or nitricline. Two peristaltic pumps with four heads each were generally available for filtration, and a third peristaltic pump with a single head, discovered mid-leg, made it possible to filter a fifth depth for DNA on 31 July 2008.

Station 1601-10a was sampled during the difficulties with the CTD rosette, and the CTD profile may be subject to errors. However, the chlorophyll maximum at 93 m, while unusual, seemed to be confirmed by Jonathanôs preliminary results.

On 29 July 2008, Marjolaine and Mariane went to the Mackenzie delta by helicopter and barge respectively, and brought back surface water for sampling (the water was not deep enough to include other depths. These samples should be very interesting, but may be of limited use because of the delay between collection and filtration, and the high sediment load. Station Mackenzie 3 was filtered in duplicate.

Live Samples
On 31 July, 2008, two 125 ml bottles were filled with seawater from the chlorophyll maximum of station CA04.08. This water was kept in the incubator at 4 °C until it could be transported back to Québec in an ice-filled cooler. It is intended to be used to establish monoclonal cultures, particularly of *Micromonas*. In addition, 1 L of 0.22 µm filtered sea water from the same station and depth was retained from DNA filtration, and kept at 4 °C until it could be transported to Québec.

ETS
The ETS was intended as a backup to measures of bacterial respiration, in which up to 8 L of seawater was filtered in duplicate through a gf/f filter from the chlorophyll maximum and surface. We had intended to collect these samples on 21 July and 31 July; however, on the 21 July we misjudged the amount of water needed to take duplicate samples. On 31 July, the number of users on our scheduled rosette precluded taking such a large quantity of water, and weather conditions prevented scheduling of an additional rosette. There is therefore only a single set of samples from 2 July.

Chlorophyll
Samples for quantifying chlorophyll in the total fraction and <3 µm fraction were collected on 21 July, 29 July and 31 July. Because the 21 July was our first full station, we decided to do only four depths so that we could familiarize ourselves with the protocol. On 29 July we sampled from the Mackenzie River delta. However, owing to the high sediment content, we were not able to filter the full amount of seawater specified by the protocol. On 31 July we sampled from six depths: bottom, O_2 minimum, nitrate minimum, nitricline, chlorophyll maximum and surface.

FISH, viral abundance
Samples for FISH were collected on 21 July, 29 July and 31 July from all available depths.

Nanoflagellate abundance
Samples for nanoflagellate abundance were filtered on 21 July, 29 July and 31 July from all available depths. Seawater was filtered onto a black polycarbonate filter and made into a slide for later counting. The amount filtered depended on the density of particles in the seawater, and ranged from 40 ml for Mackenzie 3 to 75 ml for bottom water at station 405-10a.

Bacterial abundance
Samples for bacterial abundance were usually collected together from the same casts and depths from which the nitrogen team (Mariane and Marjolaine) drew their samples. They were not collected on 20 July, 23 July or 2 August. Slides of bacterial abundance were also made whenever a bacterial respiration experiment was terminated (see below).

Ciliate abundance
Samples for ciliate abundance were collected on 21 July and 31 July.

Bacterial Respiration
Bacterial respiration was measured on samples already collected during the previous leg. Because of a delay in getting tasks organized for the first few days on the ship, there is a lacuna of several days in these measurements. On the 23 July, a crack was noticed in the light tube belonging to the light sensor of the FiBox. This crack soon became a break. An initial field repair using toothpicks and duct tape was successful and allowed measurements to continue for two more days. It was noticed, however, that measurements, while coherent with previous measurements, were generally more variable, up to 10 µmol/l, probably owing to the effect of the shipôs motion on the wobbly join. After two days, the repair broke, and further efforts were unsuccessful. All observations were therefore terminated, and slides for bacterial abundance were made from the samples.

Owing to a miscommunication, samples 1-8 were not made into slides for bacterial abundance.

Virus Abundance
Samples for virus abundance were collected on 21 July, 29 July and 31 July from all available depths. The samples were fixed with glutaraldehyde and frozen at -80 ºC.

Nitrous oxide
Samples of nitrous oxide were taken during 3 days. On 21 and 25 July two samples were taken, in triplicate, from surface and chlorophyll maximum. On July 31 three samples were taken at the same depths, and also the oxygen minimum. Samples of the atmospheric air of the deck (where the gas samples were taken) and the rosette room were also taken. The gas of each sample was taken immediately at the time of sampling, and stored in vials provided with a septum at room temperature.

MARFISH and uptake experiments
Two MARFISH experiments were carried out on July 21. The urea experiments were done with surface water and the bicarbonate and leucine experiments were done with surface and nitrocline seawater. The MARFISH filters were stored at -20ºC in petrislides until their analysis.

Bicarbonate and urea uptake experiments were also carried out, and the samples were counted in the scintillation counter.

Bacterial Production
Samples for bacterial production were taken in five stations during this leg, to complete the set of variables for the nitrogen team (Mariane and Marjolaine). These were Surface and chlorophyll only were sampled on July 26 and 28, while full profiles of four and six depths were taken on 21 July and 31 July respectively. Surface samples were taken from the Mackenzie river and two Mackenzie delta stations. These samples were processed in the RadVan, involving a 4-hour incubation in a cooler with water and ice.

Organic Matter

July 31, 4 depths of seawater were taken to get samples of fluorescent dissolved organic matter (FDOM), coloured dissolved organic matter (CDOM), amino acids, carbohydrates, dissolved organic carbon, total phosphorous and total nitrogen. The FDOM and CDOM were filtered with a GF/F filter and stored at -20 °C in amber-coloured glass bottles. Amino acid and carbohydrate samples were also filtered through a GF/F filter and stored at -20 °C in polyethylene bottles. Dissolved organic carbon samples, also filtered through a GF/F filter, were fixed with orthophosphoric acid, placed in amber-coloured glass ampoules, hot sealed and stored at 4 °C.

On July 29, a transect of stations was carried out approaching the Mackenzie delta. Organic matter samples were taken from all the 6 stations, because it is very interesting to know the influence of the river on these variables.

2.6. Team 8

PI: Gary Stern (DFO, Freshwater Institute)
Participants: Gary Stern (DFO, Freshwater Institute), Hayley Hung (Environment Canada, Torono), Amanda Chaulk (MSc student, University of Manitoba)

2.6.1. Organic contaminants

by Hayley Hung

Air sampling for persistent organic pollutants (POPs) and perfluorinated compounds

Two high volume air samplers were installed at the bow of the Amundsen to perform air sampling for organic chemicals. One sampler operated daily from July 20 until August 5; using 1 glass fiber filter to trap the particle phase and 2 polyurethane foam plugs (PUF) to trap the gaseous phase. Thirteen 24-h integrated, two 48-h integrated samples and 3 procedural blanks were taken at an average sampling rate of approximately 460 L/min. The samples will be analyze for polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), organochlorine pesticides (OCPs) and polybrominated diphenyl ethers (PBDEs). The other sampler was operated occasionally between July 18 and August 2 with three 24-h, one 34-h and one 46-h integrated samples and two procedural blanks. The sampler operates with one glass fiber filter to trap the particle phase and one PUF-XAD resin sandwich to trap the gaseous phase at an average flow rate of approximately 260 L/min. The samples will be analyzed for perfluorinated compounds. Air samples were prepared in the aft laboratory and stored in the -20 C room behind the aft laboratory.

Air sampler for perfluorinated compounds

Air sampler for POPs

2.6.2. Mercury

by Amanda Chaulk and Hayley Hung

Rationale
Mercury (Hg) levels in marine mammals and fish are an ongoing concern in Arctic regions because of their inclusion in traditional subsistence diets among indigenous peoples in northern regions. Successful strategies to mitigate health impacts related to Hg in human diets require an understanding of both the social and cultural perspective of northern communities, as well as the natural environmental processes that lead to Hg in food resources. Our research on Hg in the Arctic is focused

on determining the environmental processes responsible for the distribution and speciation of Hg in Arctic marine ecosystems, for the purpose of supporting the development of strategies to lessen the impact of Hg on human and ecosystem health.

Marine Water Column Sampling

During Leg 10 of the CFL Study, the Team 8: Contaminants group collected samples from the marine water column in Amundsen Gulf from 11 locations within the Amundsen Gulf and the Beaufort sea as well as the MacKenzie River (Table 1). Samples from the 10 m depth to the seafloor were collected with the ship-based Rosette sampling equipment in PVC ôNiskin-styleô sample bottles remotely operated from onboard the ship. Supplementary ôSurfaceô samples from 0 to 10 m in depth were collected by a PVC Niskin water sampling bottle (General Oceanics, Miami, Florida) a few hundred meters of the ship (Table 1). Within each profile, 11 to 20 different depths were sampled (including Niskin sampling), producing high resolution profiles for ótotal Hgô (Hg_T). At each depth sampled for Hg_T, water was also collected for ŭ^{18}O analysis in tightly sealed glass scintillation vials. After collection of ŭ ^{18}O samples, bottles were further sealed with parafilm and stored at 4°C. Rosettes were sampled by Hayley Hung and Amanda Chaulk. All samples were analysed in PILMS by Amanda Chaulk.

Preliminary Results

Hg_T levels in the Amundsen Gulf measured during Leg 10 were very low, averaging roughly 1 pM (0.2 ng/L) throughout the water column. These values are comparable with the lowest concentrations of Hg_T observed in the global oceans (e.g., the Pacific and North Atlantic Oceans), and somewhat lower than those observed in coastal oceans and regional seas (e.g., the Baltic and the Celtic Seas, Hudson Bay). However, we were able to observe changes in the concentrations caused by the final ice /meltbreakup and influence of river inputs from the Horton and the Mackenzie River systems.

Table 1. Sampling Location and Date for Marine Water HgT Measurements During CFL Leg 10

Station	Latitude	Longitude	Sample Type	Bottom Depth	Cast
405-10a	70o42.119	122o56.291	rosette	597	10
437	71o41.636	126o36.0	rosette	431	18
437-b	71o20.868	127o17.226	surface water		niskin
408	71o18.972	127o45.173	rosette	408	31
407	71o00.78	126o11.64	surface water		niskin
1601-10a	71o33.908	130o42.846	rosette	333	41
MR1	69o463	133o100	surface water	3.5m	niskin
MR3	69o504	133o259	surface water	3.8	grab
MR5	69o545	133o418	surface water	3.5	grab
MR8	69o633	133o449	surface water	5.3	grab
2008-10a	71o19.986	126o13.163	rosette	442	56

At open water stations, surface water samples were taken with the zodiac to avoid contamination from the ship. It was quite evident that the results from the niskin sampling were lower in THg concentration. Of course, the niskin must be cleaned and tested at both the spigot and the top of the niskin before use.

Mercury in Ice

Two ice cores collected during leg 9 (F7 and FB04) as well one collected during leg 8 (D34) were processed during leg 10. All ice cores were cut into duplicates and each duplicate was scrapped with a freshly cleaned and tested ceramic blade. Both pieces were placed into separate zip lock bags and then stored in one larger bag to melt. When sampling, each individual zip lock bag was rinsed with MQ water over the area that would be cut and then sampled. A small amount was rinsed out and then the sample was collected. For example, a 5 cm piece of ice split would yield two 25 mL samples of water in the end. The scrapping was very clean, and the gloves were changed between each section of the core to be scrapped. This is essential to good reproducible results.

Methyl Mercury

The form of mercury that accumulates within the foodweb is the organic form of mercury known as methyl mercury. We are interested in determining the pathways in which mercury (Hg) becomes methylated and to study the levels in the abiotic and biotic environments. We are up and running Methyl Mercury samples with our new and improved BrooksRand Automated system. Methyl Mercury samples were not taken this leg. However bottles were cleaned in preparation for methyl mercury sampling during ArcticNet Leg 11.

BrooksRand Automated MeHg system.

Air sampling for gaseous elemental mercury

A Tekran mercury vapour analyzer was used to measure gaseous elemental mercury (GEM) in air on the starboard side of the front deck. The analyzer is automated. It collects and analyses the air concentrations of GEM every 5 minutes at a flow rate of 1 L/min. Air concentration data are archived on a laptop connected to the analyzer.

Mercury sampling inlet

3. 2008 Circumpolar Inuit Schools on Board - Field Program

July 14 ï 25th, 2008 ï Onboard Leg 10A

Submitted by: Robin Gislason, Program Leader

Schools on Board is an outreach program of ArcticNet and the IPY-CFL study, used to promote Arctic sciences in high schools across Canada and abroad. The field program takes high school students and teachers on-board the CCGS Amundsen where they are integrated into the activities of the various science teams conducting research in the Arctic. It blends adventure, curiosity and exposure to create an energized learning environment and provides opportunities for scientists to share their passion for science and research with students ï both on the ship and in classrooms. The multidisciplinary nature of the field program demonstrates the breadth of opportunities that are available to aspiring young researchers and technicians. Face-to-face interactions with scientists of all levels (masters, PhDôs, researchers, CRC chairs) and access to state-of-the-art scientific instrumentation onboard the Canadian

research icebreaker are the focus of the on-board field program. To extend the outreach beyond the field program, experiences of those chosen to participate, are shared with fellow peers, family members and communities through a series of presentations that are delivered by the participant upon their return home.

In celebration of the International Polar Year (IPY), Schools on Board hosted three International Field Programs during the Circumpolar Flaw Lead system study (CFL). This initiative included two International Field Programs with high school students and teachers participating as well as a third Circumpolar Inuit Field Program (CIFP) which was held during Leg 10A of the CFL. As part of our commitment to education and outreach for IPY, the CIFP included collaboration with Team 10ôs Inuit Circumpolar Council Canada (ICC) and Inuit Tapiriit Kanatami (ITK). Our 10 spaces for this field program were filled by 8 students and 2 program leaders from the following regions and agencies:

Participants
Adamina Partridge- Kuujjuaq, Nunavik
Jacquenita Sammurtok ï Chesterfield Inlet, Nunavut
Logan Gruben ï Tuktoyaktuk, Northwest Territories
Lisa-Marie Alikamik ï Uluhaktok, Northwest Territories
James Kuptana ï Sachs Harbour, Northwest Territories
Ralph Sinnok, Shismaref, Alaska
Daniel Marco Keilsen Holm - Nuuk, Greenland
Evgeniya Yar ï Moscow, Russia

Program Leaders
Scot Nickels, ITK ï Ottawa, Ontario
Robin Gislason, University of Manitoba ï Winnipeg, Manitoba

Participants were selected by committee. Collaborating organizations included Schools on Board, Inuit Circumpolar Council (ICC Canda, Greenland, and Alaska) and Inuit Tapiriit Kanatami (ITK). Participants met in Inuvik, July 14th. Prior to boarding the ship, participants engaged in cultural and community activities in Inuvik, NT. These included: a visit to the Visitor Centre; activities at the Great Northern Arts Festival; a boat tour of the MacKenzie Delta with local Inuit tour guide, Gerry Suilig, and interactions with youth and community leaders in Inuvik.

A highlight of the Inuvik community visit included a one-day workshop, July 16th, on the analysis and dissemination of the Traditional Knowledge (TK) students collected from their home communities before participating in the field program. The workshop was held at the Inuvialuit Regional Corporation Boardroom and included opening remarks from Nellie Cournoyea. The inspiring words from Nellie were well received by the participants and helped to set the stage for the group discussions on how to work with the TK research the participants collected.

The group chartered a flight from Inuvik to Kugluktuk and boarded the ship at 2:00pm on July17th, 2008. Our Schools on Board group arrived onboard hours before the crew and scientists of Leg10A. This turned out well as the participants were allowed time to unpack organize their rooms and get acquainted with life onboard a research vessel. The next day saw the students immediately integrated in the activities of the CFL science teams. The program included science lectures, lab activities and fieldwork. Details of the on-board program are posted on the IPY-CFL website (www.ipy-cfl.ca). Daily dispatches including a report, photos and ship location were sent to both, IPY-CFL and ArcticNet central, to be posted on their websites. This two-week adventure into Arctic research exposed circumpolar Inuit students to the research objectives and methods of numerous science teams representing a number of research disciplines from institutions across Canada and abroad. See attached table.

In addition to hands-on research activities the program included information and sessions on various aspects of climate change in Canadaôs North, including traditional knowledge, art, culture, history, and

politics. A major outreach project of the Schools on Board CIFP was the Youth/Elder/ Scientist Knowledge Exchange held July 22, 2008 onboard the CCGS Amundsen. Schools on Board invited community members and elders from Sachs Harbour, NT onboard for this inspiring one-day knowledge exchange. The morning consisted of ship and lab tours for the students and community members. Most scientists and crewmembers were able to participate by being in their labs and work areas as the tour went through the ship to explain their work and research.

The afternoon was spent in the Officerôs boardroom where youth and elders had the opportunity to break into small groups to discuss knowledge exchange between Inuit youth and elders in current times. Each group then presented their findings to the larger group. The afternoon session ended with presentations from Captain Stéphane Julien and Chief Scientist Gary Stern on the CCGS Amundsen and the science of the CFL project. The evening event included a panel discussion on the importance of the CFL project and the current relationship between researchers and northern communities. Members of the panel included: Chief Scientist, Gary Stern, Schs Harbour Elder, John Keogak, CCGS Amundsen Captain Stephane Julien, and CIFP youth participant, James Kuptana.

The CIFP participants were able to present their research on the traditional knowledge and climate change observations collected in their communities prior to the field program. The audience for the evening events included Sachs Harbour community members and elders, scientists, crew, and CIFP participants.

The following day, July 23rd, the CIFP participants along with a number of scientists, departed the ship for Sachs Harbour, NT. A community feast was held to celebrate the previous dayôs Elder/Youth/Scientist Workshop. The feast included a number of traditional Inuit dishes as well as informal exchanges between community members, participating CIFP students, and IPY-CFL scientists.

Outreach

Based on participant and scientist evaluations, activities of the Schools on Board program were successful in raising awareness of:

1. the Schools on Board program and its educational objectives
2. the IPY-CFL program and its scientific objectives
3. the role of traditional knowledge in scientific research

A unique feature of this field program was a pre-trip activity that engaged participants in the collection of traditional knowledge using Traditional Knowledge Kits developed by Schools on Board with the financial assistance of the Walter & Duncan Gordon Foundation. This activity was central to the field program and an anticipated follow-up activity planned in a collaboration with the Institute for International Sustainable Development (IISD) Circumpolar Youth Internship program. Outreach activities planned for this program include attendance and presentation at the Arctic Changes 2008 conference and the Arctic Climate Change Youth Forum in Quebec City, December 2008; presentation at the upcoming AGU conference in San Fransisco, December, 2008; presentation at the upcoming Arctic Frontiers conference, Tromso, Norway, January 2009); publication of process and results of TK activities.

Website & dispatches

The primary communication tool for the program was the webpage hosted on the IPY-CFL and ArcticNet websites. These sites were used to deliver program details and relevant application information. The site was a very effective tool, as it also contained all of the necessary science information relevant to the science project and the Amundsen. During the field program, participants submitted daily dispatches (July15-24th, 2008) to the CFL website and the ArcticNet Expedition logbook. These sites included text and pictures describing daily activities and interactions between scientists and participants. They allowed communities, schools, friends, and families to share the experience, as well as provided visitors to the website (general public and other scientists) with detailed information of this outreach initiative.

Media continues to show an interest in the program. They include (but are not limited to):

1. Various newspaper articles and radio interviews prior to departure in each respective community
2. Interviews and ongoing media coverage onboard the Amundsen with Chris Yakk, Inuvialuit Communications Society
3. Participants featured in The Drum (ICC Alaska newsletter)
4. Interviews with NewsNorth and CBC-North ï Inuvik

In conclusion, this first 2008 Schools on Board Circumpolar Inuit Field Program was a great success. The circumpolar Inuit perspective fulfilled our mandate to broaden our outreach activities on a global and cultural scale during IPY. The overwhelming positive feedback received from all stakeholders (participants, communities, and scientists) indicates that this program is welcomed in both science and northern communities.

Participating Scientist and CCGS Crew, 2008 Circumpolar Inuit Field Program

Date	Participant	Session	Position	Affiliation
July 18	Gordon, Liz	Introduction to wildlife monitor techniques	Wildlife Monitor	Inuvialuit Regional Corporation, Team 10
July 18	Barber, Doug	Introduction to photoshop	CFL Photographer	IPY-CFL
July 18	Tremblay, Olivier	Logistics and Safety tour	Officer	CCGS
