Abstract

The reliability of asphalt pavement design depends on the accuracy of material characterization. The dynamic modulus ($|E^*|$) of asphalt concrete is the main parameter in both structural and performance models of asphalt layer, and its accuracy contributes significantly to the reliability of pavement analysis. This thesis deals with the determination of $|E^*|$ for mechanistic-empirical pavement design. Published studies have clearly identified three issues that may affect the accuracy of $|E^*|$. Firstly, predictive techniques for estimating $|E^*|$ from mixture volumetric properties are widely used in pavement design and evaluation when the measured values are not available. The reliability of these techniques is lowest at high service temperatures above 35°C. Rutting is one of the major distresses in asphalt pavements and is considered highly sensitive to $|E^*|$ at high temperatures. Secondly, $|E^*|$ is measured or predicted as a function of frequency. Since the vehicular pulse loads are represented in the time domain, the correctness of the selected $|E^*|$ for the multilayered elastic analysis depends on the accuracy of the conversion from pulse loading time to the testing frequency. The mechanistic-empirical pavement design guide (MEPDG) assumes that the loading frequency is the inverse of the pulse time. This approach overestimates the frequency and leads to unconservative pavement design. Finally, the asphalt mixtures are conveniently characterized with $|E^*|$ master curves developed from values measured at a wide range of temperature and frequency. However, stiffness of in-service asphalt concrete is limited to the resilient or backcalculated moduli because the thickness of the asphalt layer, in most cases, is less than the required height of $|E^*|$ specimens. The objective of this thesis is to

improve the reliability of pavement design and evaluation through the followings: improving the prediction of $|E^*|$ at high temperature; determining the $|E^*|$ master curve from the resilient modulus; and proposing a method to determine the frequency of the pulse loading to assign $|E^*|$ for the multilayered elastic analysis.

The relationship between $|E^*|$ at high temperature and the aggregate gradation represented with a new gradation parameter is examined. The correlation between $|E^*|$ at high temperatures and the gradation parameter improved when it was carried out independently on fine- and coarse-graded mixtures. The new parameter shows the ability to describe the effect of aggregate gradation on the stiffness at high temperatures even for as-constructed asphalt concrete. Reasonable results were predicted for the calibration data and a validation dataset from the literature. For fine-graded mixtures, a linear regression model is developed to predict $|E^*|$ at 40°C and it is used to adjust the $|E^*|$ master curve obtained with the predictive techniques. The adjustment improved the predicted moduli at high temperatures.

A viscoelastic method is proposed to calculate the frequency of a pulse load to determine the applicable $|E^*|$ for pavement design. The method can be used to calculate the frequency of any shape of loading pulse and to investigate the effect of the mixture type. Conversion equations from loading time to the frequency are developed for both field and laboratory pulses. The loading frequencies of the M_R pulse that has a loading period of 0.1 second and the FWD pulse load are 5 Hz and 15.7 Hz, respectively. The MEPDG approach overestimates the loading frequency up to 173%.

A method is proposed for predicting $|E^*|$ from M_R measured. The method applies a conversion equation to determine the frequency of the loading pulse, the parabolic interpolation function to determine $|E^*|$ at various temperatures, and the shift factor of the binder to substitute the shift factor of the mixture. Predicted $|E^*|$ values at various temperatures and frequencies are an acceptable substitution for measured $|E^*|$ values at these conditions.

1 Introduction and Problem Statement

1.1 Introduction

Asphalt concrete (AC) is a composite material consisting of fine and coarse aggregates and asphalt binder. AC is used for paving roads and parking lots to provide a smooth, quiet, and skid-resistant surface. The loading response of aggregates is considered nonlinear elastic. The asphalt binder, on the other hand, is sensitive to temperature and loading rate, and it ages with time due to exposure to ultraviolet rays and extreme temperatures. Thus, factors governing the loading response of AC are the responses of its component materials, temperature, loading rate and strain level.

AC pavements exhibit deterioration due to a number of distresses such as rutting, fatigue cracking and low temperature (thermal) cracking. The deterioration affects the serviceability and structural integrity of pavements, thus increasing the maintenance costs and reducing the pavement service life. An accurate and representative characterization and design of asphalt concrete under a diverse range of traffic and climatic conditions is essential to reduce the deterioration and to improve the prediction of pavement performance.

Yoder and Witczak (1975) identified three essential elements for any rational pavement design procedure: (1) the theory used to predict the failure or distress

parameter; (2) the evaluation of the pertinent material properties necessary for the theory; and (3) the determination of the relationship between these material properties and the failure or distress parameter. According to Uzan (1996), the load-based deformation of AC consists of elastic, plastic, viscoelastic (VE) and viscoplastic (VP) components. The elastic and plastic components are time-independent deformations, while the VE and VP components are time-dependent deformations. He also found that a VE component is present at any temperature and loading rate. Based on the strain level and the number of loading cycles, Di Benedetto et al. (2001) classified VE behaviour of asphalt concrete to three typical domains. The first domain is the linear viscoelastic (LVE) with strain of less than 100 microstrains and less than a few hundred cycles. The second domain is the nonlinear viscoelastic with high strain and low number of loading cycles. The third domain is fatigue with strain below the LVE limit and a high number of load cycles ($>10^6$). Asphalt pavement is designed to fail within the fatigue domain to sustain traffic loads with high number of repetitions.

A complex dynamic modulus (E^*) is a stress-strain relationship of LVE materials, such as AC at small strains, under a continuous sinusoidal load. Due to the viscous property, the strain lags behind the stress with a phase angle (ϕ); therefore, E^* is a complex number that can be represented by its magnitude ($|E^*|$) and ϕ. $|E^*|$ is the ratio of the sinusoidal stress amplitude to the recoverable strain amplitude. $|E^*|$ is measured at a number of temperature and frequency, and it is used to develop the $|E^*|$ master curve, which is unique curve for each mixture.

$|E^*|$ is an important AC parameter for mixture evaluation and pavement design. The

panel of the National Cooperative Highway Research Program (NCHRP) project 9-19, "SuperPave Support and Performance Models Management," selected $|E^*|$ as a primary simple performance candidate to be used with SuperPave mix design method (NCHRP 2007). That is because $|E^*|$ is highly correlated to rutting and fatigue cracking (Witczak et al., 2002a, 2002b). Furthermore, $|E^*|$ is a required input in the Mechanistic-Empirical Pavement Design Guide (MEPDG) developed in NCHRP project 1-37A, "Development of the 2002 Guide for the Design of New and Rehabilitated Pavement Structures" (NCHRP 2004). $|E^*|$ is incorporated in both pavement structural and pavement performance models to calculate the stress, strain and displacement and to predict rutting and fatigue cracking. Through the $|E^*|$ master curve, the effect of traffic speed, temperature and aging can be integrated in pavement models. Moreover, $|E^*|$ as a fundamental AC property has relationships, through the viscoelastic theory, with the time-dependent AC stiffnesses such as creep compliance $D(t)$, and relaxation modulus $E(t)$ that are determined under constant stress and strain, respectively. $D(t)$ is efficiently used to predict low-temperature distress, and $E(t)$ is used in LVE analysis of asphalt pavement.

There are two methods to determine $|E^*|$: laboratory testing and predictive models. MEPDG recommends measuring $|E^*|$ in the advanced pavement design (level 1) and using the predictive models that can estimate $|E^*|$ in the less sophisticated and less reliable designs (level 2 and level 3). The complexity of the laboratory testing as well as the limited capability of AC testing systems forces pavement engineers to rely on level 2 and level 3 to characterize AC (Zeghal et al., 2005 and Zeghal and Mohamed, 2008).

3

In addition to $|E^*|$, a resilient modulus (M_R) of AC is used for mixture characterization and in-service pavement evaluation. M_R is obtained from a repeated test in the indirect tensile (IDT) mode by applying a pulse load followed with a rest period. In the IDT mode, cylindrical specimens are loaded diametrically between two curved loading strips and the deformations are collected along the loading direction and perpendicular to it. The M_R test may be carried out on laboratory compacted specimens and field AC cores. Generally specimen preparation is easier in M_R test than in $|E^*|$ test, however M_R specimens can be damaged more easily due to cracking at the contact area between loading strips and the specimen. In addition, the $|E^*|$ test is more reliable and results in more consistent data compared to the M_R test.

1.2   Problem Statement

The accurate determination of $|E^*|$ of asphalt concrete is imperative for more reliable pavement design and evaluation. Three issues will be addressed to improve determination of $|E^*|$ for mechanistic-empirical pavement design.

1. Improving $|E^*|$ prediction at high temperatures

There has been significant progress in developing predictive models that rely on material and mixture volumetric properties to determine $|E^*|$. The Witczak $|E^*|$ predictive model (Witczak and Fonseca, 1996) is perhaps the most used one since it is incorporated in MEPDG (NCHRP 2004). Pellinen (2001) evaluated the model and concluded that "*the Witczak et al. model needs further evaluation to accurately predict the volumetric components influenced upon $|E^*|$*". Dongré et al. (2005) found

that the model can not detect the deviation of the mixture volumetric properties, aggregate gradation or binder content, from the mix design levels, and that the current methods of predicting $|E^*|$ are least reliable at high service temperatures such as those close to 40°C. The low reliability of $|E^*|$ prediction reduces the reliability in the forecasted pavement performance and its estimated service life. In this thesis, the relationship between $|E^*|$ at 40°C, $\left|E^*_{40}\right|$, and the aggregate gradation of mixtures is investigated using a new gradation ratio (GR). In addition, a $\left|E^*_{40}\right|$-GR model has been developed for fine-graded mixtures to improve $|E^*|$ predicted from models such as the Witczak model.

AC pavements in cold climate regions such as Manitoba exhibit low temperature cracking and rutting that are related to temperature. The resistance of AC to low temperature cracking depends mainly on the temperature susceptibility of the asphalt binder. This cracking can be reduced by using binder with lower stiffness than the one used at hot climate regions. The low stiffness binder allows AC to shrink at cold temperatures without building critical tensile stress causing the cracking but makes AC more susceptible to rutting at high temperatures. AC pavements at cold climate regions experience rutting at lower service temperatures than those temperatures at hot climate regions. The resistance of AC to rutting as a high temperature distress depends mainly on aggregate characteristics in asphalt mixtures.

According to MEPDG, $|E^*|$ is an essential AC parameter in modeling of AC rutting and improving its prediction especially at high temperatures increases the reliability

in prediction of rutting. Modeling of low temperature cracking does not require $|E^*|$ but parameters of the indirect tensile creep compliance at temperatures -30°C to 0°C.

2. Pulse Loading Time-Frequency Conversion for Representative $|E^*|$ for Elastic Analysis Asphalt Concrete

$|E^*|$ is obtained from laboratory measurements and predictive models as a function of frequency (f). For an elastic AC pavement analysis, the pulse loading time (t_p) is used to calculate f (Hz) at which $|E^*|$ is considered as an elastic stiffness. MEPDG, which utilizes a multilayer elastic analysis for the pavement system, has adopted an approach considering that f (Hz) is the inverse of t_p (s). Dongré et al. (2006) concluded that the MEPDG approach does not have scientific support and suggested using the angular frequency (ω) (rad/s) instead of the frequency (Hz) for the conversion. Both approaches have been under examination due to the high modulus they estimate (Underwood and Kim, 2009). This issue was discussed by the Federal Highway Administration (FHWA) and Expert Task Group (ETG) on Asphalt Fundamental Properties and Advanced Modeling in its 2006 and 2007 meetings (FHWA and ETG minutes, 2006 and 2007). Al-Qadi (FHWA and ETG minutes, 2007) concluded that the two approaches are incorrect and further investigation for the relationship between the testing frequency and the loading time was recommended. Recently, Al-Qadi et al. (2008b) used Fast Fourier Transformation (FFT) to determine the frequency content of field measured stresses. They calculated f (Hz) as the dominant frequency obtained from the weight centres of the frequency spectrum. Although FFT can determine the frequency content of the pulse stress, the

dominant frequency does not account for the viscoelastic property of AC. The thesis has contributed a pulse time-frequency conversion approach that is based on the viscoelastic theory and equal recoverable strains resulting from both pulse and sinusoidal stresses. The approach can be applied to determine the equivalent frequency of either laboratory or field loading pulses. Adopting this approach in pavement design may result in equal critical AC strains from both the viscoelastic and elastic analysis thus predicting more realistic load-related pavement performance.

3. Predicting the dynamic modulus from the resilient modulus

According to AASHTO TP62-03 "Standard Method of Test for Determining Dynamic Modulus of Hot-Mix Asphalt Concrete Mixtures", the $|E^*|$ test is carried out on gyratory compacted specimens that are cored and sawed to a 100 mm diameter and a 150 mm height. The required specimen height restricts the test to laboratory compacted specimens, and even if it is possible to extract 150 mm cores from in-service pavement, in most cases, they will be composed of two or more AC layers having different properties. Since $|E^*|$ is a required input for pavement evaluation and rehabilitation, its determination is imperative for in-service pavement.

The in-situ layer modulus is determined using the falling weight deflectometer (FWD) and back-calculation analysis (NCHRP 1-37A). This methodology provides the stiffness value at one single pavement temperature for an AC layer. For complete characterization of AC as a viscoelastic material, stiffness is required at a wide range of temperature and loading rate.

Recently, Lacroix et al. (2008) used an artificial neural network (ANN) to predict $|E^*|$ from M_R. The ANN was trained with a database containing $|E^*|$ of mixtures and M_R that is calculated from this database. Using the trained ANN for predicting $|E^*|$ of in-service asphalt concrete from M_R may result in significant errors since the training data is from laboratory compacted mixtures. The accuracy of ANN depends on the range of the training data. Harran and Shalaby (2007a) concluded that the compaction type has a significant effect on AC stiffness where different $|E^*|$ values were obtained from laboratory compacted specimens and field cores. In this thesis, a method to predict $|E^*|$ from M_R has been introduced and can be applied to laboratory compacted specimens or extracted field cores.

1.3 Objectives of the Thesis

1. To evaluate methods of determining $|E^*|$ including the shifting techniques required for constructing the $|E^*|$ master curve.

2. To improve the reliability in the prediction of $|E^*|$ at high temperatures through evaluating the relationship between $|E^*|$ at 40°C and the aggregate gradation, developing the $\left|E^*_{40}\right|$-GR model and using it to adjust the predicted $|E^*|$ master curves.

3. To convert the pulse loading time to testing frequency to assign $|E^*|$ as an AC elastic modulus in the pavement elastic analysis. The pulse time-frequency conversion approach will be based on the viscoelastic theory, and it can calculate frequency of field and laboratory pulse stresses.

4. To predict $|E^*|$ from M_R of asphalt concrete. The pulse loading time of M_R is converted to an equivalent frequency using the conversion approach proposed to fulfil the third objective of this thesis. An interpolation function will be examined to determine $|E^*|$ required for developing the entire master curve.

1.4 Scope and Research Methodology

The scope of the thesis is limited to fine-graded AC mixtures, which are the prevailing type of mixtures in Manitoba. The research program consists of testing specimens prepared in the laboratory and AC cores extracted from in-service pavements. The mixtures were prepared from aggregates and binder samples that were obtained from recent highway projects in Manitoba and the cores were extracted from recent paved highways. Some of these mixtures were specified for wear-resistant surface courses and others were specified for binder courses.

$|E^*|$ and ϕ of AC were measured in the axial compression mode according to AASHTO TP62-03 from specimens compacted in the laboratory . M_R is measured according to the protocol of the long-term pavement performance (LTPP) project 07 from laboratory compacted mixtures and in-service AC cores that are extracted from pavements immediately after construction. $|E^*|$ and M_R are measured in the linear viscoelastic range where the strain does not exceed 150 microstrains.

2 Literature Review

2.1 Rheology of Asphalt Concrete

Asphalt concrete (AC) is a composite material consisting of mineral aggregates and an asphalt binder. Mechanical properties of AC vary with composition, temperature, loading rate (frequency) and strain level. Goodrich (1991) evaluated the influence of the following factors on the rheology of AC: the composition of AC, the effect of aggregates and the effect of binder, using a dynamic mechanical analyzer (DMA). He found that the contribution of each factor to the rheology of asphalt mixtures largely depends on temperature whereas:

- At low temperature (below $10^{\circ}C$), the binder rheology has the dominant influence.

- At medium temperature (10 to $50^{\circ}C$), the change in the binder rheology has small effect on the magnitude of the rheology of AC.

- At high temperature (above $50^{\circ}C$), aggregate properties dominate the rheology of AC and the rheological differences of the binders are not apparent. Thus mixture stability at high temperatures should be achieved with good mix design rather than binder rheology change.

Goodrich (1991) concluded that properties of AC change from linear viscoelastic (LVE) with hereditary characteristics at low temperatures, low loading times or high loading frequencies and low strain levels, to nonlinear elasto-visco-plastic at high temperatures,

low frequencies and high strain levels.

Uzan (1996) evaluated the response of AC to the applied load using the repetitive axial creep test and concluded that:

- The deformation of AC under loads consists of four components, elastic, plastic, viscoelastic (VE) and viscoplastic (VP), as shown in Figure 2.1. The elastic and the plastic deformations are time-independent while the VE and VP components are time-dependant. The elastic component rebounds completely after removing the load while the plastic one accumulates producing permanent deformation. The VE deformation is recoverable while the VP component is a rate-dependant plasticity.

- The dominant deformation component depends on temperature and loading time.
Figure 2.1: Components of asphalt concrete deformation (Uzan, 1996)

- The VE component is present at all temperatures and loading times and should be considered in any constitutive law for an accurate characterization of asphalt concrete to calculate the state of stress and the strain in the pavement structure.

Di Benedetto et al. (2001) classified AC behaviour based on the magnitude of strain and the number of loading cycles to three typical domains. (1) The linear viscoelastic (LVE) domain is relevant to the small strain ($<10^{-4}$) and few hundreds of loading cycles. Christensen and Anderson (1992) described AC behaviour as LVE when small strain remains small. (2) The nonlinear viscoelastic domain is pertinent to high strain magnitudes and few loading cycles. (3) The fatigue domain is related to the small strain ($<10^{-4}$), LVE strain, combined with a high number of load cycles ($>10^{6}$). Asphalt concrete is designed to fail within the fatigue domain to sustain traffic loads with high number of cycles.

2.2 Linear Viscoelastic Response Functions of Asphalt Concrete

The relaxation modulus ($E(t)$), creep compliance ($D(t)$) and complex modulus (E^{*}) are fundamental response parameters that have been used to characterize LVE behaviour of asphalt concrete. While $E(t)$ and $D(t)$ are measured in the time domain, E^{*} is measured in frequency domain. Using one of these response parameters for AC characterization depends on the loading application and the condition under which the material is characterized and difficulty of determining the response in the laboratory.

2.2.1 Time –Dependent Response Function

$D(t)$ is determined by applying a constant stress (σ_0) and simultaneously measuring the corresponding strain history ($\varepsilon(t)$) while $E(t)$ is obtained by applying a constant strain, ε_0, and measuring the stress history, $\sigma(t)$. $D(t)$ and $E(t)$ can be defined respectively as follows:

$$D(t) = \frac{\varepsilon(t)}{\sigma_0} \tag{2.1}$$

$$E(t) = \frac{\sigma(t)}{\varepsilon_0} \tag{2.2}$$

$D(t)$ and $E(t)$ are not the inverse of one another and the relationship between them can be obtained from the following Equation(2.3)

$$\int_0^1 E(t-\tau)\frac{dD(\tau)}{d\tau}d\tau = 1 \tag{2.3}$$

where τ is the integration variable.

Christensen (1992) stated that, at low temperatures and low strain levels, $D(t)$ and $E(t)$ tests can be accurately used to model the VE property of AC . At high temperatures and high strain levels, the plastic deformation of AC is much higher than the VE deformation, thus the $D(t)$ and $E(t)$ tests may produce unrealistic characterization of AC and should not be used at these conditions. Generally, $D(t)$ is used for modeling cold temperature distresses while $E(t)$ is used to determine the stresses and strains under applied loads. The E^* and cyclic creep compliance (D^*) tests have been used efficiently to characterize AC especially at small loading times.

$D(t)$ can be expressed with the power law that has three material constants (D_0, D_1 and m)

13

as follows:

$$D(t) = D_0 + D_1 t^m \qquad (2.4)$$

The D_0, represents the elastic compliance while D_1 and m represent the long time loading

(creep). Kim et al. (2005) introduced an approach to determine these constants accurately

from the results of the dynamic and static creep tests. D_0 is obtained from results of the

cyclic creep test and then used to determine D_1 and m from results of the static creep test.

When both the stress and strain are changing with time, which is the case for the traffic

loading, Equations (2.1 and 2.3) are not valid. For unaged material, the uniaxial stress and

strain are related through the following convolution integrals:

$$\sigma(t) = \int_0^t E(t - \tau) \frac{\partial \varepsilon(\tau)}{\partial \tau} d\tau \qquad (2.5)$$

$$\varepsilon(t) = \int_0^t D(t - \tau) \frac{\partial \sigma(\tau)}{\partial \tau} d\tau \qquad (2.6)$$

2.2.2 Dynamic (Complex) Modulus (Frequency-Dependent Response Function)

The complex modulus of AC is a LVE property that depends on temperature and loading

frequency. It is a stress-to-strain relationship under a continuous sinusoidal load. Due to

the viscous property of AC, the strain lags behind the stress, Figure 2.2(a), (Witczak et

al., 2002a). The stress and the corresponding strain are sinusoidal whereas strain are

represented as follows:

$$\sigma = \hat{\sigma} \sin(\omega t) \qquad (2.7)$$

$$\varepsilon = \hat{\varepsilon} \sin(\omega t - \phi) \qquad (2.8)$$

where: $\hat{\sigma}, \hat{\varepsilon}$ = peak-to-peak stress and strain respectively,
(a)
(b)

Figure 2.2: Parameters of the dynamic modulus test

(a) Stress-strain relationship. (b) Complex modulus components.

t = time, s

ω = angular velocity; rad/s, where $\omega = 2\pi f$ and f is the frequency of the load, Hz

ϕ = phase angle, degree.

Thus the complex modulus (E^*) can be represented by the following:

$$E^* = \frac{\sigma_o \sin(\omega t)}{\varepsilon_o \sin(\omega t - \phi)} = \frac{\sigma_o}{\varepsilon_o}\cos\phi + i\frac{\sigma_o}{\varepsilon_o}\sin\phi \tag{2.9}$$

E^* can be written in the following form:

$$E^* = E' + iE'' \tag{2.10}$$

Equation (2.10) represents a complex plane, Figure 2.2(b), where the real and imaginary parts are the storage (E') and loss (E'') moduli, respectively. Furthermore, E^* can be represented by a polar coordinate system including a radial coordinate, which is the dynamic modulus ($|E^*|$), and a polar angle, ϕ. $|E^*|$ can be obtained as follows:

$$\left|E^*\right| = \sqrt{(E')^2 + (E'')^2} = \frac{\hat{\sigma}}{\hat{\varepsilon}} \tag{2.11}$$

Both $|E^*|$ and ϕ characterize the viscoelastic behaviour of AC. For a given $|E^*|$ and ϕ, E' and E'' can be calculated as follows:

$$E' = |E^*| \cos \phi; \text{ and} \tag{2.12}$$

$$E'' = |E^*| \sin \phi \tag{2.13}$$

Generally, a material can be described based on ϕ as follows:

- $\phi = 0$; elastic material,

- $\phi = 90$; viscous material, and

- $\phi = 0 - 90$; viscoelastic (VE) material such as AC.

16

2.3 Thermo-rheologically Simple Principle

Asphalt concrete is a thermo-rheologically simple (TRS) material in the linear viscoelastic stage (Kim and Lee, 1995). The TRS means that the VE properties at a given temperature and loading rate can be obtained either at lower temperatures and longer loading times or at higher temperatures and shorter loading times (Chehab et al., 2002). By applying TRS, which is also called the time-temperature superposition principle, a viscoelastic property measured at various temperatures and loading times/frequencies can be represented with either temperature or loading time/frequency while holding the other one constant. For example the dynamic modulus measured at various temperatures and frequencies, $|E^*|$ (f, T), is represented with one continuous curve, known a master curve, at a given reference temperature (T_0). The $|E^*|$ master curve is a unique relationship between $|E^*|$ and frequency at the reference temperature and can be represented as follows:

$$|E^*| (f_r) = |E^*| (f, T) \text{ at the reference temperature } (T_0) \qquad (2.14)$$

where: f_r is the reduced frequency and can be calculated as follows:

$$f_r = \frac{f}{a(T)}, \text{ and } a(T) \text{ is the shift factor at temperature } (T)$$

Figure 2.3 illustrates the typical procedure of constructing the $|E^*|$ master curve. $|E^*|$ at each temperature is shifted a specific value, shift factor, to align the master curve at T_0. The master curve represents the time dependency of AC and the shift factor is a function of temperature and represents the AC temperature dependency. Both the $|E^*|$ master curve and the shift function are required for complete VE characterization over a wide range of frequencies (times) and temperatures.

(a) $|E^*|$ master curve, (b) Shift factor-temperature relationship

2.4 Shifting Techniques

Two ways have been used to obtain the shift factors of asphalt mixtures for constructing a $|E^*|$ master curve: using the shift equations of binders and an experimental method proposed by Pellinen et al. (2004). These shifting equations are as follows:

- Williams, Landel and Ferry (WLF) equation,

- Viscosity-temperature susceptibility (VTS) equation,

- Arrhenius equation,

- Log-linear equation.

2.4.1 WLF Equation

The WLF equation defines the shift factor at a temperature above the glass transition state, the change from a viscous or rubbery condition to a hard and relatively brittle condition, of the binder. The WLF equation is represented by Equation (2.15).

$$\log[a(T)] = \frac{-C_1(T - T_g)}{C_2 + T - T_g} \qquad (2.15)$$

where:

$a(T)$ = shift factor

T_g = glass transition temperature, $^\circ$C

T = temperature, $^\circ$C, where T > T_g

C_1, C_2 = constants

The WLF equation describes the temperature susceptibility of the asphalt binder over temperatures -20°C to 60°C. Pellinen et al. (2004) found that constants of the WLF equation, C_1 and C_2, vary from a mixture to another.

2.4.2 Arrhenius Equation

The Arrhenius equation assumes that the relaxation time of the creep behaviour of binder is proportional to the thermal energy $(R.T)$ required to overcome the activation energy barrier (ΔE_a).

$$\log[a(T)] = \frac{\Delta E_a}{2.303R}\left(\frac{1}{T} - \frac{1}{T_0}\right)$$

(2.16)

where:

ΔE_a = activation energy, J/mol

R = universal gas constant = 8.314472 J/°K-mol,

T, T_0 = temperature and reference temperature, °K

Dongre' et al. (2005) found that activation energy, ΔE_a, depends on the binder type where the binder was characterized by a Useful Temperature Range (UTR), which is the algebraic sum of the high and low temperatures for continuous performance grade (PG) of asphalt binders. For example, UTR of PG 51-27 binder is 78°C, which is the sum of 51 and 27. ΔE_a was correlated well (R^2 = 0.90) to UTR and the relationship was shown by Equation (2.17).

$$\Delta E_a = 2484.7 \text{ UTR} - 43168.0$$

(2.17)

where

UTR = Useful Temperature Range, °C

2.4.3 Log-linear Equation

The Log-linear equation assumes that the relationship between the logarithm of the shift

factor at a given temperature is proportional to the difference between the given and reference temperatures. It can be represented by Equation (2.18):

$$\log[a(T)] = \beta(T - T_0)$$

(2.18)

where

β = constant, and

T, T_o = given and reference temperatures (°C) respectively

2.4.4 VTS Equation

The temperature susceptibility model of binders can be used to calculate the shift function using Equation (2.19):

$$Log[a(T)] = C(10^{A+VTS\,\log(T_R)} - 10^{A+VTS\,\log(T_{oR})})$$

(2.19)

where

C =constant,

A, VTS = viscosity-temperature susceptibility parameters of the binder

T_R,   =temperature, Rankin (°R)

T_{oR} = reference temperature, Rankin (°R)

The constants A and VTS can be obtained from the viscosity-temperature relationship, which is defined by:

$$\log(\log(\eta)) = A + VTS\,\log(T_R)$$

(2.20)

where

η = viscosity (cpoise)

The viscosity (η) is obtained by conducting the dynamic shear rheometer (DSR) test on

21

binders at an angular velocity (ω) of 10 rad/second. It can be calculated from the DSR test parameters, the complex shear modulus (G^*) and phase angle (δ), using Equation (2.21):

$$\eta = \frac{G^*}{10}\left(\frac{1}{\sin\delta}\right)^{4.8628}$$

(2.21)

Using Equation (2.21) to calculate the shift factor enables one to integrate the binder rheological property in the $|E^*|$ master curve, for example integrating the aging effect into the AC stiffness. MEPDG incorporates A-VTS model to predict $|E^*|$ (NCHRP, 2004).

2.4.5 Experimental Method

The experimental method is a shifting technique in which no shift function is used to obtain the shift factor. The method applies the nonlinear fitting technique to determine the shift factors and parameters of a master curve simultaneously. Pellinen et al. (2004) compared the five shift techniques. The experimental method produced master curves with the best goodness of fit, which is represented with the ratio of the standard error to the standard deviation (S_e/S_y), compared to the other shifting techniques. The reason is that the method has the most flexibility because no function is assigned. The method was recommended for shifting $|E^*|$ values. The shift factor calculated from Arrhenius Equation was found to be comparable to the one obtained from the experimental method.

Chehab et al. (2002) demonstrated that AC is thermorheologically simple (TRS) in tension even with growing damage, thus the shifting technique is applicable even with growing damage. The time-temperature superposition principle can be applied with growing damage and viscoplastic straining. Chehab et al. stated that this principle helps

to reduce the testing program, develop strength and corresponding strain master curves as a function of reduced time, predict stress-strain curves obtained from the crosshead strain test, and simplify the thermorheological analysis of a pavement structure.

2.5   Complex Modulus Representation

2.5.1   Dynamic Modulus Master Curve

The $|E^*|$ master curve of an AC mixture is a unique curve for each mixture and has the following benefits:

- To characterize AC over a wide range of temperatures and loading frequencies for pavement design and evaluation.

- To compare AC mixtures over a wide range of frequencies and temperatures.

- To determine $|E^*|$ of AC beyond the sensitivity range of the test setup and to reduce the testing program.

- To integrate factors influencing the stiffness and the performance of AC. The factors include loading time, temperature, and AC aging.

Pellinen and Witczak (2004) constructed $|E^*|$ master curves by fitting the sigmoidal function, Equation (2.22), to the measured compressive $|E^*|$ test data using nonlinear least square regression.

$$\log\left|E^*\right| = \delta + \frac{\alpha}{1 + e^{\beta - \gamma \log f_r}}$$

(2.22)

where: δ, α, β and γ = regression parameters
Figure 2.4: Sigmoidal function of |E*| master curve, after Pellinen et al. 2004

Figure 2.4 illustrates the sigmoidal function shown by Equation (2.22). δ and α are location parameters where δ represents the minimum $|E^*|$ and α represents the range of change in $|E^*|$ values. Sum of the two location parameters is the maximum $|E^*|$ value of an AC mixture. β represents location of the turning point of the master curve and γ represents the steepness of the master curve. Pellinen et al. (2004) justified using the sigmoidal function based on the physical behaviour of $|E^*|$ through the entire temperature range. $|E^*|$ at low temperatures are close to the maximum $|E^*|$ while, at high temperatures, get close to the minimum $|E^*|$. Pellinen et al. (2002) through using a k1-k3 non-linear elasticity model incorporated the stress dependency and non-linearity to the sigmoidal master curve.

2.5.2 Isothermal and Isochronal curves

The complex modulus (E^*) components, $|E^*|$ and ϕ, at various temperatures and frequencies can be illustrated using the family curves holding one variable constant (Pellinen, 2001). Isothermal curves, Figure 2.5(a), are family curves in which the temperature is held constant and isochronal curves, Figure 2.5(b), are family curves in which the frequency is held constant. The isothermal and isochronal curves are used to investigate the relationship between $|E^*|$ and the controlling variables. $|E^*|$ master curves are isothermal curves that are constructed at a reference temperature. Functions have been evaluated to represent the isochronal curve in chapter 7 to interpolate $|E^*|$ at various temperature.

2.5.3 Complex and black space planes

$|E^*|$ and ϕ can be represented using complex plane, known as Cole-Cole, and black space plane, Figure 2.6. In complex plane, the horizontal axis is the storage modulus (E') and vertical axis is the loss modulus (E''). On the black space plane, $|E^*|$ and ϕ values are plotted on the horizontal and vertical axes; respectively. The complex and black space planes are unique smooth curves for the AC mixture independent of frequency and temperature factors. The planes are used for data quality control (Pellinen et al., 2004). The complex plane shows consistency of the dynamic modulus test data at low and intermediate temperatures while black space shows the consistency of the test data at high temperatures.

2.6 Significance of Dynamic Modulus

2.6.1 Modulus of Pavement Design and Evaluation

MEPDG is the first design procedure that incorporated the impact of aging of asphalt on mixture properties over short periods of time such as biweekly and/or monthly basis through the entire design life. The guide incorporates the effect of the pavement temperature and vehicular loading time and the binder properties on AC through the $|E^*|$ master curve and the shift factor. In MEPDG, the change of temperature is predicted with the Enhanced Integrated Climatic Model (EICM) through the pavement depth. The EICM is a one-dimensional coupled heat and moisture flow model that is used to predict the change in behaviour of pavement material over the service life. The EICM is out the scope of the thesis and more information can be found in Zapata and Huston (2008). On the other hand, the loading time, which is calculated based on the stress distribution in a pavement structure and a speed of the moving load, is used in MEPDG to calculate the loading frequency. $|E^*|$ is integrated in the pavement structure and performance models used in MEPDG. The structure model provides responses: the stress, strain and displacement. The critical structure model responses are the inputs of the performance prediction models such as fatigue cracking (alligator and longitudinal), permanent deformation (rutting), and low temperature cracking.

2.6.1.1 Fatigue Cracking

The fatigue cracking performance model predicts the number of load cycles until the fatigue failure. The transfer function of the fatigue cracking, alligator and longitudinal, incorporated in MEPDG is defined by Equation (2.23).

28

$$N_f = 0.00432\overline{k}_1 C\left(\frac{1}{\varepsilon_t}\right)^{3.9492}\left(\frac{1}{|E^*|}\right)^{1.281} \tag{2.23}$$

where,

N_f = number of repetitions until fatigue failure,

ε_t = max tensile strain at bottom of AC layers, and

$|E^*|$ = complex modulus of the material.

$\overline{k}_1$ = correction parameter of different asphalt layer thickness (H_{ac}) effects.

$\overline{k}_1$ depends on type of the fatigue cracking. For the alligator cracking, it is calculated as follows:.

$$\overline{k}_1 = \left(0.000398 + \frac{0.003602}{1 + e^{(11.02 - 3.49 H_{ac})}}\right)^{-1}$$

For the longitudinal cracking, $\overline{k}_1$ is calculated as follows:

$$\overline{k}_1 = \left(0.01 + \frac{12.00}{1 + e^{(15.676 - 2.8186 H_{ac})}}\right)^{-1}$$

where,

H_{ac} = total thickness of asphalt layers, inch,

C = laboratory to field adjustment factor, where

$C = 10^M$ in which

$$M = 4.84\left(\frac{V_b}{V_b + V_a} - 0.69\right)$$

V_b = percentage effective binder content.

V_a = percentage of air voids of the AC layer

2.6.1.2 Rutting

The transfer function of AC rutting is calculated of the Equation (2.24).

$$\frac{\varepsilon_p}{\varepsilon_r} = k_1 10^{-3.4488} T^{1.5606} N^{0.479244}$$

(2.24)

where,

ε_p = permanent strain at a depth from the pavement surface of "*depth*"

ε_r = resilient strain,

T = temperature, Fahrenheit ($^{\circ}$F),

N = total number of load repetitions.

k_1 = factor accounts for the confining pressure at different depth

$$k_1 = (C_1 + C_2 depth)0.328196^{depth}$$

where,

$$C_1 = -0.1039 H^2{}_{ac} + 2.4868 H_{ac} - 17.342$$

$$C_2 = 0.0172 H_{ac} - 1.733 H_{ac} + 27.428$$

2.6.2 Simple Performance Indicator

The simple performance test (SPT) is defined in a NCHRP 9-19 report as "*A test method that measures a mixture response characteristic or a parameter that is highly correlated to the occurrence of the pavement distress (e.g., cracking and rutting) over a diverse range of traffic and climatic conditions*" (NCHRP 2002). Witczak et al. (2002b) listed specific requirements for developing the SPT:

- The SPT is to be used in support of the SuperPave volumetric mixture design

procedure.

- The SPT must test AC specimens compacted with SuperPave gyratory compactor (SGC).

- The SPT must accurately measure true fundamental responses and properties of AC mixtures.

- The SPT must be based on existing technology and equipments.

- Responses measured with the SPT need not predict the entire performance history.

- Properties determined from SPT should be tied to the advanced mixture characterization methods.

The NCHRP 9-19 research team performed an extensive test program to select a SPT for the most common distresses of asphalt concrete such as rutting, fatigue cracking and thermal cracking. The test program included over 80 test response parameters from eleven test types and mixtures and performance data from three experimental sites, the Minnesota Road (MnRoad) Project, the Federal Highway (FHWA) Accelerated Loading Facility study (ALF) and the FHWA Performance Related Specifications Study (WesTrack). The candidates for rutting were dynamic modulus, static creep, and the repeated load permanent deformation test. In a similar attempt, Witczak et al. (2002a) reported that the dynamic modulus test and the creep compliance test are the two top SPT candidates for fatigue and thermal cracking. The unconfined $|E^*|$ test in LVE was statistically the best SPT candidate for rutting, the parameters included $|E^*|/\sin\phi$, which is the highest recommended candidate performance parameter, and $|E^*|$. The analysis included unconfined and confined $|E^*|$ test at various confinement pressures, two

31

temperatures, 37.8°C and 54°C, and a frequency of 5 Hz. The parameters were measured in the linear and nonlinear viscoelastic regions.

2.6.3   Effect of Aggregate Gradation

Birgisson and Roque (2005) proposed a framework for optimizing aggregate gradation for high $|E^*|$ values. The framework relies on gradation factors proposed by Birgisson and Ruth (2002) and Ruth et al. (2002) and $|E^*|$ at high temperature (40°C). The gradation factors can be calculated for a given aggregate as follows:

1. For a given gradation with a nominal maximum particle size (NMPS), a control sieve point (P$_c$) is calculated from (0.22NMPS) and then rounded to the nearest sieve size. Control Point (P$_c$) separates the gradation of fine and coarse aggregates as shown in Figure 2.7.

2. The gradation factors of fine and coarse aggregates are the power law constants of the aggregate gradation curves of each, and are obtained as follows:

$$P = a_{fa} D^{n_{fa}} \text{ ;for fine aggregate} \tag{2.25}$$

$$P = a_{ca} D^{n_{ca}} \text{ ; for coarse aggregate} \tag{2.26}$$

where:

P: the percentage of aggregate passing at sieve diameter (D) (mm)

a_{fa}, n_{fa} : fine gradation parameters

a_{ca}, n_{ca} : coarse gradation parameters
Figure 2.7: Gradation factors of aggregates

Gradations of fine-graded mixtures fall above the maximum density line (MDL) as given by the 0.45 power gradation chart while those of the coarse-graded mixtures are typically below the MDL. It was found that fine-graded aggregates have $n_{ca} \leq 0.5$ while coarse-graded aggregates have $n_{ca} > 0.5$. The aggregate gradations of asphalt mixtures were classified into four categories as shown in the framework in Figure 2.8:

Category 1: Fine-graded aggregate with $n_{ca} \leq 0.5$ and $n_{fa} \leq 0.59$, a high stiffness mix.

Category 2: Fine-graded aggregate with $n_{ca} \leq 0.5$ and $n_{fa} > 0.59$, a moderate to low stiffness mix

Category 3: Coarse-graded aggregate with $n_{ca} > 0.5$ and $n_{fa} \leq 0.59$, a moderate stiffness

mix

Category 4: Coarse-graded aggregate with $n_{ca} > 0.5$ and $n_{fa} > 0.59$, a low stiffness mix
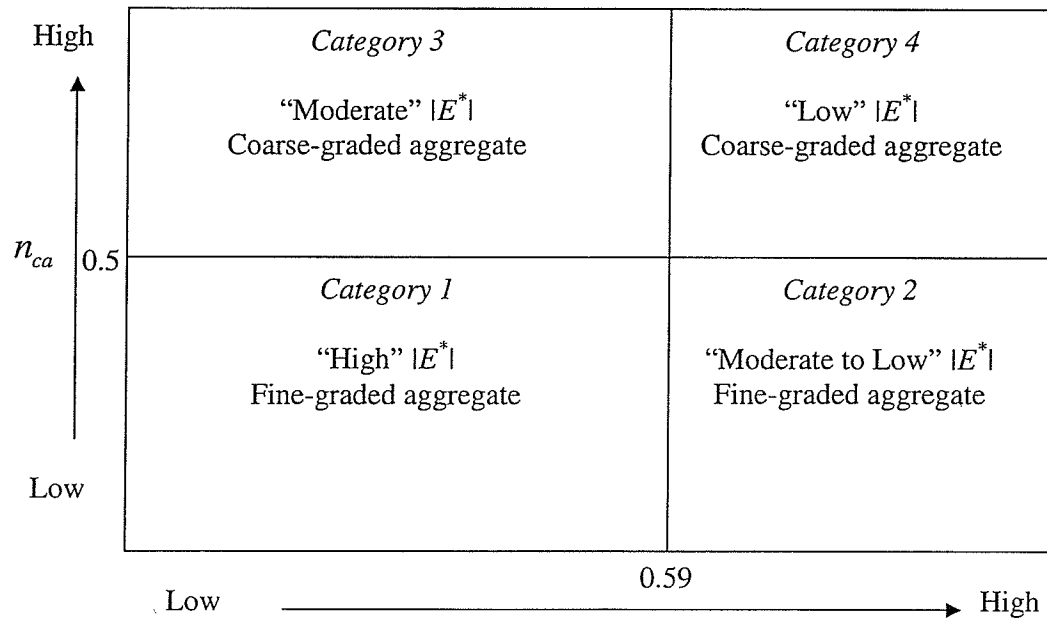

Figure 2.8: Framework for optimizing aggregate of asphalt mixtures for dynamic

modulus (Birgisson and Roque, 2005)

The framework can be used to optimize the gradation for $|E^*|$ through the selection of aggregates. It classifies fine-graded and coarse-graded mixtures as optimal or non-optimal but it does not quantify the effect of the aggregate gradation on $|E^*|$. This framework implies that the aggregate gradation has a significant effect on $|E^*|$ at high service temperatures (40°C and above). In chapter 5, the relationship between $|E^*|$ at high temperatures and gradations is evaluated to determine a gradation parameter that can describe this relationship.

2.7 Relationship between Frequency-Dependent and Time-Dependent Viscoelastic Responses

The viscoelastic response of AC is required in both time and frequency domains. For the viscoelastic analysis, the response functions are required in the time domain to consider the load history in the analysis. On the other hand, MEPDG requires the dynamic modulus in the frequency domain where the pulse loading time is converted to loading frequency. The available methods to convert the responses between the two domains are discussed below.

Kim and Lee (1996) proposed an approach to determine $|E^*|$ from the static or complex creep compliance. The relationship between E^* and the complex creep (D^*) can be written in the frequency domain as follows:

$$E^* = \frac{1}{D^*} \tag{2.27}$$

where E^* is complex number that has storage and loss modulus as in Equation (2.12 and 2.13) and D^* is assumed as follows:

$$D^* = D' - iD'' \tag{2.28}$$

where D' and D'' are the storage and loss creep compliance respectively and can be calculated at a given f using Equations (2.12 and 13) as in Equations (2.29 and 2.30):

$$D' = \frac{E'}{|E^*|^2} \quad \text{and} \quad D'' = \frac{E''}{|E^*|^2} \tag{2.29}$$

$$E' = \frac{D'}{|D^*|^2} \quad \text{and} \quad E'' = \frac{D''}{|D^*|^2} \tag{2.30}$$

35

Applying the theory of viscoelasticity, D^* and $D(t)$ can be related to each other using Laplace transformation. If $D(t)$ is represented by Equation (2.4), D^* can be determined from Equation (2.31):

$$D^* = D_0 + D_1\Gamma(m+1)\left[\cos(\frac{m\pi}{2}) - i\sin(\frac{m\pi}{2})\right]\omega^{-m} \qquad (2.31)$$

where

$$\Gamma(m) = \int_0^\infty t^{m-1}e^{-t}dt \qquad (2.32)$$

where

$\Gamma(m)$ is Gamma function

$\omega = 2\pi f$ and it is the angular frequency (rad/second).

Comparing Equations (2.28) and (2.31), D' and D'' respectively are as follows:

$$D' = D_0 + D_1\Gamma(m+1)(2\pi f)^{-m}\cos(\frac{m\pi}{2}) \qquad (2.33)$$

$$D'' = D_1\Gamma(m+1)(2\pi f)^{-m}\sin(\frac{m\pi}{2}) \qquad (2.34)$$

The procedure described by Equations (2.29 to 2.34) is applied in chapter 6 to determine the creep compliance parameters, D_0, D_1 and m, from $|E^*|$ and ϕ of the tested materials at various temperatures. The parameters represent AC materials in an approach to determine the equivalent frequency for a loading time.

2.8   Pulse Loading Time –Testing Frequency Relationship

A major milestone of MEPDG is considering the effects of the pavement loading time (t_p) and temperature on AC behaviour (NCHRP 2004). MEPDG calculates t_p as a function of

36

the vehicle speed and pavement layer stiffness and thicknesses by applying the Odemark approach and the method of 45° influence zone of the vertical stress (NCHRP 2004). Equation (2.35) is used to calculate the design frequency (*f*) of $|E^*|$.

$$t_p = \frac{1}{f} \tag{2.35}$$

In an independent review of the MEPDG, NCHRP (2006) documented that *"In its present form, the Guide procedure for estimating complex modulus in the HMA layers results in unrealistic values, particularly for thick layers, showing a decrease in predicted modulus with depth in hot weather that is counterintuitive. This quandary results from the loading time/frequency effect overriding the temperature effect"*. These shortcomings have motivated many researchers and discussions. Some of these discussions can be found in two consecutive meeting minutes of 2007 and 2008 of the FHWA Asphalt Fundamental Properties and Advanced Modeling Expert Task Group (FHWA and ETG minutes, 2006 and 2007).

Al-Qadi et al. (2008a) identified two major sources of the inaccuracy in the procedure adopted in MEPDG for estimation the frequency of $|E^*|$. The first source of inaccuracy is incapability of Odemark approach to account for the effect of the far-wheel loads. The second source is the conversion from the pulse loading time to the testing frequency.

Factors affecting the calculated loading time by applying the MEPDG approach according to Al-Qadi et al. (2008a) are

- The elastic solution to calculate the loading time can not account for the far-field effect of an approaching-leaving rolling wheel,

37

- The elastic solution does not consider the delayed response of AC,

- The accurate rheology of binder may not be captured in the MEPDG, and

- The accuracy of Odemark approach to calculate the loading time is uncertain and it requires validation since it is empirical.

Al-Qadi et al. (2008b) used 3-D Finite Element (FE) viscoelastic analysis to adjust the loading time calculated by Odemark approach. The viscoelastic properties of AC was calculated using $|E^*|$ and ϕ. A correction factor as a function of pavement depth and pavement functional class was proposed to adjust the MEPDG frequency. The correction factor was calculated as follows. First, the loading time at various pavement depths was calculated from the calculated history of the vertical stress at a given point. Then the FE loading frequency was calculated using Equation (2.35). The correction factor is the ratio between the FE frequency and the one calculated in accordance with the MEPDG.

The second source of the inaccuracy is the conversion method applied by MEPDG. Dongre et al. (2006) reviewed the common conversion methods between the time and frequency domains in the field of rheology and concluded the followings:

- No supporting reference other than MEPDG for Equation (2.35) was found.

- The angular frequency (ω) in rad/second is widely used and the conversion can be represented as in Equation (2.36). Using ω was explained as consequence of the Inverse Fast Fourier Transformation (IFFT) of the storage or loss modulus.

$$t_p = \frac{1}{\omega} = \frac{1}{2\pi f} \qquad\qquad (2.36)$$

Underwood and Kim (2009) evaluated four solution techniques that are based on linear viscoelastic principles to determine $|E^*|$ that gives the same maximum response of AC subjected to a sinusoidal pulse stress. The solutions utilize the static and complex creep compliances that are calculated from $|E^*|$ and ϕ and they are as follows:

1. Linear viscoelastic analysis: in which, the maximum strain is calculated from the strain history and can be represented as in Equation (2.37)

$$\varepsilon_0 = \max\left[\int_0^t D(t-\tau)\frac{d(\frac{\sigma_0}{2}\sin(\omega\tau-\frac{\pi}{2})+\frac{\sigma_0}{2})}{d\tau}d\tau\right] \qquad (2.37)$$

2. Quasi-static analysis, the maximum strain is calculated from Equation (2.38)

$$\varepsilon_0 = \max[D(t)\sigma(t)] \approx D(\frac{t_p}{2})\sigma_0 \qquad (2.38)$$

3. Steady-state analysis, the maximum strain is calculated as follows:

$$\varepsilon_0 = \left|D^*\right|_{f=1/t_p}\sigma_0 \qquad (2.39)$$

The source of error in adopting this approach is considering that the stress is steady-state sinusoidal input with zero mean stress. These conditions are not met by traffic loading (Underwood and Kim, 2009).

4. Superposition analysis; this approach separates the haversine pulse to a sinusoidal portion and constant loading portion. The maximum strain is calculated as follows:

$$\varepsilon_0 = \sigma_0\left(\frac{\left|D^*\right|_{f=1/t_p} + D(\frac{t_p}{2})}{2}\right) \qquad (2.40)$$

39

These solutions provide considerable insight to calculate AC stiffness that account for the maximum strain instead of the recoverable strain. The maximum strain consists of the instantaneous recoverable strain and the creep strain, which releases within the rest period. The calculated stiffness at t_p is less than $|E^*|$ at frequency calculated according to MEPDG approach. These solutions have two main shortcomings:

- The solutions are based on a sinusoidal loading. Many equations as shown in Table 2.1 have been used to fit the measured or calculated stress to determine the pulse time. Al-Qadi et al. (2008b) found that haversine or bell-shape forms represent the normalized compressive stress for moving loads. Equations (2.41 and 2.42) represent the normalized haversine and bell-shape stresses; respectively

$$\sigma(t) = \sin^2(\frac{\pi}{2} + \pi \frac{t}{t_p}), \text{ where } -\frac{t_p}{2} \leq t \leq \frac{t_p}{2} \qquad (2.41)$$

$$\sigma(t) = e^{-t^2/s^2} \qquad (2.42)$$

where

s: standard deviation that control the shape of the curve.

Table 2.1: Different fitting functions used for pulse calculation (Al-Qadi et al., 2008b)

Approximation function	Source of AC stress distribution
Sinusoidal and triangular function	FE modeling and elastic theory
log (t_p)=0.5d-0.2-0.94 log (v)	Elastic layered theory
Square wave function	Proposed
Haversine and normalized bell-shape functions.	Field stress measurements

d = pavement depth (m), v = vehicle speed (km/h)

40

The solutions require both $|E^*|$ and ϕ to calculate the creep compliances. The current MEPDG version does not use ϕ in pavement design. Incorporating these solutions requires significant changes in MEPDG. Al-Qadi et al. (2008b) suggest that conversion of the field loading pulse to the frequency domain should be carried out using the Fast Fourier Transformation (FFT) for the following reasons:

- Conversion factors are based on the pulse shape in the time domain.

- There is no specific function to fit the field loading pulse under encountered conditions (pavement depth, material stiffness and vehicle speed).

- Symmetric functions can not account for the delayed AC response and the residual stress

- The pulse generated by vehicular loading includes complex frequency spectrum. The simple conversion forms shown by Equation (2.35 and 2.36) may not provide reliable conversion.

Al-Qadi et al. (2008b) used the dominant frequency to represent the frequency spectrum of a pulse stress. The dominant frequency was defined as the weight centre of the frequency spectrum. This definition neglects the property of the material that the stress is applied on. For example, the dominant frequency for a pulse is constant whether the material is elastic or viscoelastic.

A novel approach is introduced in chapter 6 of this thesis to determine the frequency of a pulse stress. The approach utilizes the viscoelastic theory to determine the frequency of $|E^*|$ that is calculated from normalized sinusoidal stress and the maximum strain of a normalized pulse stress.

2.9 Determination of AC Dynamic Modulus

2.9.1 Laboratory Testing

The $|E^*|$ test can be carried out according to ASTM 3497 (ASTM 2003) "Test Method for Dynamic Modulus of Asphalt Concrete" and AASHTO TP 62-03 (2005) "Determining Dynamic Modulus of Hot-Mix Asphalt Concrete Mixtures". There are some differences between ASTM 3497 and AASHTO TP 62-03. ASTM 3497 recommends conducting the test on cylindrical specimens with a height-to-diameter ratio of 2 to 1, a minimum specimen diameter of 101.6 mm (4 in) and four or more times the maximum nominal size of aggregate. It recommends carrying out the test at 5, 25 and 40°C and frequencies of 1, 4 and 16 Hz at each temperature. The major difference between the two test methods is that, the test based on ASTM 3497 can be carried on laboratory prepared specimens and field cores.

On the other hand, AASHTO TP 62-03 was developed during the National Cooperative Highway Research Program (NCHRP) projects 9-19 " SuperPave Support and Performance Models Management" and NCHRP 9-29 "Simple Performance Tester for SuperPave Mix Design". Figure 2.9 shows a schematic diagram for the test setup. AASHTO TP 62-03 requirements are as follows:

- Mixtures should be aged for 4 hours to represent the short-term aging that occurs for the mix during the mix placement and compaction

- The test specimens are prepared in the laboratory from 170-mm gyratory specimens by coring and sawing. Test specimens have dimensions of 100 mm diameter and 150 mm height with a height to diameter ratio of 1.5 to 1

42
Figure 2.9: Schematic of dynamic modulus test (AASTHO TP 62-03)

- The test is conducted at temperatures of -10, 4.4, 37.8 and 54.4°C, and frequencies 0.1, 0.5, 1, 5, 10 and 25 Hz.

- End friction reducer (EFR) should be used to diminish the effect of friction developed between the specimen ends and the loading platens. EFR consists of

two latex sheets filled with silicon grease.

- Amplitude of the sinusoidal stress shall be adjusted at each test sequence to produce resilient axial strain between 50 and 150 micro-strains.

AASHTO TP 62-03 has been recommended to determine $|E^*|$ and ϕ of asphalt mixtures for pavement design and evaluation under MEPDG and under the SPT.

2.9.2 Indirect Tensile Testing Mode

Kim et al. (2004) presented a linear viscoelastic (LVE) solution to determine $|E^*|$ and ϕ using indirect tensile (IDT) testing mode. In IDT testing, the cylindrical specimen is instrumented with two transducers on each face to measure horizontal and vertical deformations and loaded diametrically via two loading strips with the sinusoidal load. Figure 2.10 shows schematic of the IDT testing. $|E^*|$ is measured in IDT testing mode, $IDT|E^*|$, is calculated using Equation (2.43).

$$IDT\left|E^*\right| = \frac{2P_0}{\pi a d} \frac{\beta_1 \gamma_2 - \beta_2 \gamma_1}{\gamma_2 V_o - \beta_2 U_0} \tag{2.43}$$

where;

P_0 = amplitude of the sinusoidal load.

a = loading strip width, m

d = thickness of the specimen, m

V_0, U_0 = amplitude of the vertical and horizontal displacements.

$\beta_1, \beta_2, \gamma_1, \gamma_2$ = coefficients that depend on the specimen diameter and gauge length as shown in Table 2.2.
Figure 2.10: Schematic of indirect tension (IDT) test

Table 2.2: Coefficients of dynamic modulus and Poisson's ratio from indirect tensile method; specimen diameter of 150 mm

Gauge Length (mm)	β_1	β_2	γ_1	γ_2
25.4	-0.0065	-0.0021	0.002	0.0062
38.1	-0.0099	-0.0032	0.0029	0.0091
50.8	-0.0134	-0.0042	0.0037	0.0116

Harran and Shalaby (2007b) found that the variability in $|E^*|$ obtained from the uniaxial

testing carried out according to AASHTO TP62-03 is higher than the variability of $|E^*|$

measured from IDT testing.

Kim et al. (2004) recommended to carry out $IDT|E^*|$ at 5, 25 and 40°C and eight frequencies at each temperature. Although the approach was verified for laboratory compacted specimens, it may not be feasible for extracted AC cores from in-service pavement. The high number of the test sequences on the cores may produce significant damage especially for cores collected from damaged pavement.

Pellinen et al. (2006) used composite $|E^*|$ testing to determine stiffness of thin surface layers. This testing is carried out on rectangular specimens that are sawed from the surface layer cores, and then stacked horizontally without bonding. The ends are hydrostone caped to provide flat and smooth loading area and to bond the blocks. The complexity of the specimen preparation may affect the viability of this approach (Biswas and Pellinen, 2007). In chapter 7, predicting $|E^*|$ master curve from M_R is introduced and can be used for predicting $|E^*|$ of in-service from laboratory measurements.

2.10 Variability of Dynamic Modulus

The sources of variability of $|E^*|$ are material, mixing and compaction process, preparation of test specimens and specimen instrumentation. AASHTO TP62-03 recommends an accuracy limit that depends on the number of test specimens and the number of the transducers required to measure the axial strain of the specimen. In general, AASHTO TP 62-03 recommends maximum limits of the accuracy of ±15% of the mean values.

$|E^*|$ test data depends on the two test parameters, temperature and frequency. Tran and

Hall (2006) used the variability of measured $|E^*|$ to evaluate different test protocols using different number of specimens and instruments to measure deformation. The variance is applied to measure the variability in $|E^*|$. The variability in measurements of the $|E^*|$ test is measured with both "within" the specimen and "between" the test specimens. The variability within the test specimen at given conditions is defined by Equation (2.44)

$$S_w^2 = \frac{1}{m-1} \sum_{i=1}^{m} (X_{is} - \overline{X}_s)^2 \tag{2.44}$$

where:

S_w^2 = "within" specimen variance

X_{is} = dynamic modulus of the specimen at position of the transducer (i)

$\overline{X}_s$ = average of the dynamic modulus at the transducers within the specimen

m = number of the transducers on the test specimen

The "between" specimen variance at given test conditions is calculated from Equation (2.45)

$$S_b^2 = \frac{1}{n-1} \sum_{j=1}^{n} (\overline{X}_{sj} - \overline{X})^2 \tag{2.45}$$

where:

S_b^2 = "between" specimens variance

$\overline{X}_{sj}$ = average dynamic modulus of specimen (j)

$\overline{X}$ = average of three samples

n = number of specimens

The variance of the dynamic modulus is sensitive to the test conditions: temperature and frequency. Coefficient of variation (CV) which is the normalized value of the variance is used to represent the variation. The average of the "within" specimen coefficient of variation (CV_w) and the "between" coefficient of variation (CV_b) are as follows:

$$CV_w = \frac{1}{n}\sum_{j}^{n}\frac{S_{wj}}{\overline{X}_{sj}}$$

(2.46)

$$CV_b = \frac{S_b}{\overline{\overline{X}}}$$

(2.47)

where:

S_{wi} = the variance within specimen i

Accuracy of the measured $|E^*|$ in terms of standard error (S_e) is defined using "within" specimen and "between" specimen variances by the relation:

$$s_e = \sqrt{\frac{CV_w^2}{m}+\frac{CV_b^2}{n}}$$

(2.48)

Tran and Hall (2006) found that number of test specimens and the number of measurement instruments affixed on each specimen significantly affect the variability of $|E^*|$ but the accuracy limit specified with AASHTO TP62-03, 15%, can be reached by using two specimens and two LVDTs on each specimen.

2.11 Dynamic Modulus Predictive Models

The dynamic modulus is best estimated from non-destructive laboratory testing at various loading frequencies and test temperatures (NCHRP 2004). On the other hand, there has

48

been significant progress in developing predictive models that can estimate $|E^*|$ without the need for testing. Such models rely on material and mixture volumetric properties to predict $|E^*|$. The models such as the Witczak model and Hirsch model are widely used in planning and design of projects in which laboratory testing is unavailable.

2.11.1 Witczak $|E^*|$ Model

The model was developed through comprehensive work initiated by Shook and Kallas (1969) and completed by Witczak and his associate research team at the University of Maryland since the early 1970s until 1990s (Pellinen 2001). The database includes $|E^*|$ test data conducted at the Asphalt Institute, University of Maryland, and Federal Highway Administration (FHWA). The revised Witczak model can be found in Witczak and Fonseca (1996). The revised Witczak model is shortly called the Witczak model and it is as shown by Equation (2.49).

$$
\begin{aligned}
\log\left|E^*\right| = {} & 3.750063 + 0.02932\,p_{200} - 0.001767\,(p_{200})^2 - 0.002841\,p_4 \\
& - 0.058097\,V_a - 0.802208\left(\frac{V_{beff}}{V_{beff} + V_a}\right) \\
& + \frac{3.871977 - 0.0021\,p_4 + 0.003958\,p_{38} - 0.000017\,(p_{38})^2 + 0.00547\,p_{34}}{1 + e^{-0.603313 - 0.31335\log(f) - 0.393532\log(\eta)}}
\end{aligned}
\tag{2.49}
$$

where,

$\left|E^*\right|$ = dynamic modulus, psi,

P_{200} = percentage passing sieve #200,

P_4 = cumulative percentage retained on the 4.75-mm (#4) sieve,

P_{38} = cumulative percentage retained on the 9.5-mm (#3/8) sieve,

P_{34} = cumulative percentage retained on the 19-mm (#3/4) sieve,

V_{beff} = percentage effective bitumen content, by volume,

49

V_a = percentage air content,

f = frequency, Hz, and

η = bitumen viscosity, 10^6 Poise.

The viscosity (η) is incorporated in the predicting $|E^*|$ models to represent the effect of temperature and the asphalt aging. The viscosity-temperature relationship is shown by Equation (2.20). The regression constants, A and VTS, are determined by two methods. In the first method, the constants are obtained by regression analysis between viscosity and temperature using Equation (2.20). The viscosity of the binder at various temperatures is calculated from complex shear modulus, G^*, and phase angle, δ, of binder using Equation (2.50).

$$\eta = \frac{G^*}{10}\left(\frac{1}{\sin \delta}\right)^{4.8628}$$

(2.50)

In the second method, A and VTS are typical values for a given PG grade binder and they can be found in NCHRP 1-37A.

Several researchers, such as Dongré et al. (2005), Birgisson et al. (2005) and Schwartz (2005), evaluated the Witczak $|E^*|$ predicting model. Generally, the predicted and measured $|E^*|$ values are in good agreement. Pellinen (2001) reported that the Witczak model does not capture the mixture performance with sufficient accuracy, for the model to be used as a simple performance test, and that additional mixture volumetric evaluation is required to predict $|E^*|$ accurately. Schwartz (2005) concluded that the model understates the influence of the mixture parameters, and can not differentiate the performance of different mixtures under identical conditions. Dongré et al. (2005)

evaluated the Witczak model for hot mix asphalt plant mixtures, and concluded that the model loses accuracy if the mixture volumetric properties, aggregate gradation and binder content, deviate from the mix design levels. They found that the accuracy of the Witczak model was lowest at high temperature and that below an $|E^*|$ value of 125,000 psi (862 MPa) the model over-predicts $|E^*|$. Therefore, they recommended measuring $|E^*|$ if the expected value is below 125,000 psi (862 MPa). Rutting, one of the major pavement distresses, is considered highly sensitive to $|E^*|$ at high service temperatures. The low reliability of the $|E^*|$ predictive models at high temperatures devalues the reliability of the predicted rutting. Therefore, considering the difficulty of obtaining high quality measurements of $|E^*|$, it is essential to improve the prediction models at high temperature.

Birgisson and Roque (2005) proposed a framework for optimizing aggregate gradation for high values of $|E^*|$. This framework implies that aggregate gradation has a significant effect on the dynamic modulus at high temperatures. It ranks the mixtures according to their stiffness at high temperature but it does not quantify the effect of the aggregate gradation on $|E^*|$.

Schwartz (2005) performed a sensitivity analysis on the predicted $|E^*|$ for the input parameters of the Witczak model. The analysis was performed with the same data used to calibrate the Witczak model. The analysis showed that the aggregate gradation parameters have the strongest influence and, between the gradation parameters, the percent retained on the 4.75 mm sieve and the percent passing the 0.075 mm sieve have the strongest influence on the predicted $|E^*|$.

In chapter 5, a regression model has been developed to adjust the predicted $|E^*|$ master curve using an aggregate gradation parameter. The model was developed from $|E^*|$ test results of mixtures tested at the University of Manitoba and other tests that are available in the published literature.

2.11.2 Hirsch model

The Hirsch model can be used to predict properties of composite materials, such as AC, from their phases and volume fractions. Christensen et al. (2003) modified the Hirsch model to estimate $|E^*|$ and ϕ of AC. The modified model serves as a tool for analyzing the effect of the changes in volumetric mix factors of AC. They reported that the model is rational and simple. The Hirsch model uses three parameters, namely, the complex shear modulus of binder ($\left|G^*\right|$), the void in mineral aggregate (VMA), and the void filled with asphalt (VFA) to predict $|E^*|$ and ϕ. The calibrated Hirsch model is shown by Equation (2.51).

$$
\begin{aligned}
\left|E^*\right| = P_c & \left[4.2 \times 10^6 (1 - \frac{VMA}{100}) + 3\left|G^*\right|_{binder} \left(\frac{VFA \times VMA}{10^4} \right) \right] \\
& + (1 - P_c) \left[\frac{1 - \frac{VMA}{100}}{4.2 \times 10^6} + \frac{VMA}{3VFA\left|G^*\right|_{binder}} \right]^{-1}
\end{aligned} \tag{2.51}
$$

where

$\left|E^*\right|$ = dynamic modulus, psi

$\left|G^*\right|_{binder}$ = complex shear modulus of binder, psi

VMA = voids in the mineral aggregate, %

VFA = voids filled with asphalt, %

P_c = aggregate contact factor where

$$P_c = \frac{\left(20 + \dfrac{VFA \times 3\left|G^*\right|_{binder}}{VMA}\right)^{0.58}}{650 + \left(\dfrac{VFA \times 3\left|G^*\right|_{binder}}{VMA}\right)^{0.58}} \qquad (2.52)$$

$\left|G^*\right|$ is measured at various temperatures and frequencies using the DSR test. A model was proposed to predict phase angle at various temperatures and frequencies using the aggregate contact factor, P_c, Equation (2.53).

$$\phi = -21(\log P_c)^2 - 55 \log P_c \qquad (2.53)$$

They compared the Hirsch model shown by Equation (2.51) with the Witczak model shown by Equation (2.49). $|E^*|$ calculated from the two models are in good agreement and of similar accuracy. The Witczak model is used in pavement design and evaluation by MEPDG, therefore it has been evaluated by researchers. In chapter 4, the evaluation is carried out on the Witczak model for asphalt mixtures used in Manitoba because Manitoba, which is in a cold region, uses low stiffness binders to reduce thermal cracking due to cold temperatures (<5°C).

2.12 Resilient Modulus

The resilient modulus of asphalt concrete is an elastic property that is defined by the ratio

of the applied repeated stress (σ_a) to the resilient strain (ε_r) as follow.

$$M_R = \frac{\sigma_a}{\varepsilon_r} \qquad (2.54)$$

M_R is obtained from the cyclic test in indirect tensile (IDT) mode by applying a pulse load followed by a rest period. In the IDT mode, cylindrical specimens are loaded diametrically against two loading strips and the horizontal and vertical deformations are measured simultaneously at centres of the specimen ends over a specific gauge length, Figure 2.11. According to ASTM D4123, M_R test may be carried out on laboratory compacted specimens as well as AC cores. LTPP 07 recommends a haversine pulse with a loading time of 0.1 s followed by rest period of a 0.9 s to determine M_R. Other pulse forms and loading times may be applied according to ASTM D4123. Table 2.3 lists differences between $|E^*|$ test and M_R test.
Figure 2.11: Typical load and deformation of resilient modulus test

Table 2.3: Comparison between resilient modulus and dynamic modulus

Criteria	Dynamic modulus ($|E^*|$)	Resilient modulus (M_R)
Test standards	ASTM 3497, AASHTO TP 62-03	ASTM D4123, SHRP P07, NCHRP 1-28 and 1-28A
Response range	Linear viscoelastic	Elastic
Load form	Continuous sinusoid	Pulse load
Loading time/frequency	25, 10, 5, 1, 0.5 and 0.1 Hz	One loading time (0.1 s)
Rest period	None	0.9 s
Testing mode	Axial compression	Indirect tensile (IDT)
Test specimen size	100 mm diam × 150 mm height	150 mm diam × 50 mm thickness
Specimen preparation	Lab compacted specimens	Lab compacted specimens and field cores
Compaction method	Gyratory	Marshall and Gyratory
Pavement design guide	NCHRP 1-37A	AASHTO1993
Relation to pavement performance	Correlated to rutting and fatigue cracking (Witczak et al. 2002a and 2002b)	Was not investigated
Measures creep compliance, relaxation modulus:	Yes (Daniel and Kim, 1998)	None

While M_R test can be performed on field cores, the required height of 150 mm restricts the $|E^*|$ test to laboratory compacted specimens. Even if it is possible to extract 150 mm cores from in-service pavement, in most cases they will be composed of two or more courses having different properties. Generally speaking, specimen preparation is easier in M_R test than in $|E^*|$ test , however M_R specimens can be damaged more easily due to cracking at the contact points between loading strips and specimens. In addition the $|E^*|$ test is more reliable, resulting in less variance compared to the M_R test.

A method to convert M_R to $|E^*|$ is useful for testing as-built and in-service pavements. This method can support using the M_R test for quality control (QC) since the M_R test is cheaper and faster to conduct, and for level 2 mix design, large improvements without the need to create new mixes or carry out the $|E^*|$ test. Furthermore, the method can be beneficial for adapting the existing asphalt pavement databases, such as the LTPP database, to MEPDG.

Any reliable method to convert M_R to $|E^*|$ should address the following three differences: the test configuration, load form and definition of the recoverable deformation.. First, the $|E^*|$ test is carried out in the axial compressive mode while the M_R test is performed in the IDT mode. Second, the load of $|E^*|$ is sinusoidal applied at multi frequencies while the load of M_R is pulsed and carried out at one loading time. Finally, the deformation history of $|E^*|$ specimens is a continuous sinusoid and the recoverable deformation is its amplitude. In contrast, the deformation history of M_R specimens consists of two components resulting during the pulse load and the rest period. The recoverable

deformation of the M_R testing is defined with empirical process by using a method illustrated by ASTM 4123 and LTPP 07 as in Figure 2.11 with line 1 and line 2.

Kim et al. (2004) introduced an analytical linear viscoelastic solution to determine $|E^*|$ in the IDT mode. The solution was verified with experimental measurements obtained from the axial compression mode. The verification implies that the test configuration does not have an impact on the stiffness when the applied stress is in the viscoelastic range.

Nunn (1996) suggested the equivalent frequency (f_{eq}) at which the stiffness modulus under a continuous sinusoidal load is determined is equivalent to the modulus determined under a pulse load. To calculate f_{eq}, the viscoelastic property of asphalt concrete was represented with the Burgers model, which includes three elements connected in series: spring, dashpot and Kelvin elements. Although this model represents well the behaviour of the viscoelastic material under a constant load, it does not capture exactly the strain over long-term loading. Loulizi et al. (2006) calculated f_{eq} from the pulse loading time (t_p) by using the following relationship.

$$f_{eq} = \frac{1}{2\pi\omega} = \frac{1}{2\pi t_p} \tag{2.55}$$

This approach treats the asphalt concrete as an elastic material and neglects the influence of the rest period on the recoverable deformation.

Lacroix et al. (2008) used an artificial neural network (ANN) to predict $|E^*|$ from M_R. The ANN was trained with $|E^*|$ of the Witczak database and M_R calculated from this database using an approach proposed by Lacroix et al. (2007). Since the accuracy of

ANN depends on the range of the training data, errors could result from extrapolating M_R. Using the trained ANN for predicting $|E^*|$ of in-service asphalt concrete could result in significant errors since the training data was based on laboratory compacted mixtures only. In chapter 6, a numerical approach is proposed to determine the equivalent frequency for the loading time of pulse. This approach was used to predict $|E^*|$ from M_R in chapter 7.

3 Materials and Experimental Program

3.1 Testing Plan

The research program required the determination of the $|E^*|$, ϕ and M_R of laboratory asphalt mixtures and in-service asphalt concrete. Figure 3.1 shows the testing plan. This testing plan is a part of a comprehensive testing plan of a project carried out at the University of Manitoba in cooperation with Manitoba Infrastructure and Transportation (MIT). In this project, test procedures were established for the first time in Manitoba to measure $|E^*|$, ϕ, M_R, $D(t)$ and IDT strength of asphalt concrete according to the current standards (Harran and Shalaby, 2008) .

59

The sources of asphalt concrete consisted of AC mixtures prepared in the laboratory from loose aggregates and binders sampled from asphalt pavement projects and in-service AC extracted immediately after construction. The mixtures were tested in the axial compression mode to determine $|E^*|$ and ϕ and in the indirect tensile mode to determine M_R, $|E^*|$ and ϕ. The in-service AC cores were tested only in the indirect tensile mode to determine M_R, $|E^*|$ and ϕ.

3.2 Field Sampling

Field samples consisted of loose aggregates, loose binders, and the in-service AC cores taken from pavement projects constructed in Manitoba, Canada during the period from 2001 and 2004. Generally, the asphalt concrete layer of asphalt pavement constructed in Manitoba consists of surface and binder courses, as shown in Figure 3.2.
Figure 3.2: Typical cross section of asphalt pavement (not to scale).

The surface mixtures, denoted by S followed by a project number, contained crushed stone to meet the surface layer requirements. On the other hand, the binder mixtures, denoted by B followed by the project number, contained fine river gravel and may contain reclaimed asphalt pavement (RAP). Table 3.1 lists locations of pavement sections from which the loose aggregates and binders were collected and the field AC cores were extracted. Table 3.1 shows also whether the mixtures and cores from the surface course or the binder course. The samples were collected from Provincial Trunk Highways (PTH) and Provincial Roads (PR).

61

These sites are a representative sample of AC mixtures selected in cooperation with MIT to characterize the asphalt concrete mixes used in Manitoba. Collecting the field samples and preparing the mixtures from the loose material were completed by MIT. The mechanical test program shown in Figure 3.1 was carried out in the Pavement Research Laboratory at the University of Manitoba. The loose aggregates and binders were sampled from materials specified for surface and binder courses of four projects constructed during 2004. The collected aggregates and the binders were stored in sealed containers until the day of preparation of test specimens.

The field AC cores were drilled through the whole depth of the bituminous layers from the 13 pavement sections immediately after construction. Thus, the cores were not exposed to damage from the traffic loads or from long-term aging. Twelve field AC cores were extracted from each pavement section in accordance with the test protocol of the LTPP project P07. The cores were taken from the between, outer and inner wheel paths. They were extracted using 150 mm diameter core drill with a water-soluble coolant. The field AC cores were put in plastic bags, wrapped with plastic sheets, and stored in freezers until testing to prevent the ambient effects on the core properties.

3.3 Properties of Sampled Aggregate and Binder

Eight mixtures, S1-S4 and B1-B4, were prepared in the laboratory by duplicating the proportions of the aggregates and the binders of the field mixtures. Table 3.2 lists properties of the sampled aggregates. B1 and B2 included RAP percentages of 15% and 46% respectively of the total weight of the aggregates but the shown gradations are for the

new aggregates only. The nominal maximum particle size (NMPS), according to SuperPave definition, is one sieve size larger than the first sieve to retain more than 10 percent. NMPS of all aggregates is 12.5 mm except for S4 and B2, NMPS is 19 mm and 9.5 mm respectively.

Table 3.2: Properties of the sampled loose aggregate

Mixture	Gradation							Specific Gravity	Water Absorp-tion (%)
	Percent passing (%)								
	19 mm sieve	12.5 mm sieve	9.5 mm sieve	4.75 mm sieve	2 mm sieve	0.425 mm sieve	0.075 mm sieve		
S1	100	91.6	79.3	61.8	47.0	29.6	3.5	2.638	2.05
S2	100	90.2	79.0	61.9	49.0	26.9	3.6	2.667	0.93
S3	100	90.2	80.0	63.5	50.7	24.0	5.2	2.481	3.22
S4	100	86.7	77.3	61.8	49.6	28.9	3.7	2.66	1.16
B1, 15% RAP	100	94.4	86.3	71.9	53.0	25.5	4.1	2.634	1.62
B2, 46% RAP	100	96.0	91.9	77.1	60.3	34.4	6.9	2.652	1.58
B3	100	91.9	88.3	77.5	61.6	25.6	5.0	2.457	3.50
B4	100	93.2	85.6	69.9	56.8	30.7	4.2	2.642	1.01

Figures 3.3 and 3.4 show aggregate gradations plotted on the 0.45-power chart where the gradation charts are grouped by the aggregate type and NMPS. The mixtures were classified as fine-graded based on location of the gradation curves with respect to the maximum density line (MDL) of the 0.45-power chart. The gradations of fine-graded mixtures fall above MDL while those of the coarse-graded mixtures typically fall below MDL.

(b) S4, nominal max particle size of 19 mm

Figure 3.3: Aggregate gradation of surface mixtures
(a) B1, B3 and B4, nominal max particle size of 12.5 mm
(b) B2, nominal max particle size of 9.5 mm

Figure 3.4: Aggregate gradation of binder mixtures

65

Table 3.3 lists performance grades (PG) of the binders and the average binder contents of the field mixtures. For mixtures that contain RAP, PG is for the unaged binders and the binder content is the sum of the contents of RAP binder (aged binder) and the unaged binders, which serve as a rejuvenator. The dynamic shear modulus ($|G^*|$) and the phase angle (δ) of the binders were obtained from published work (Shalaby, 2002) and were used, herein, to determine coefficients of the viscosity-temperature relationship (A and VTS). $|G^*|$ and δ were measured by the dynamic shear rheometer (DSR) test at a temperature range of 7°C to 70°C and a natural frequency (ω) of 10 rad/sec. Appendix A lists $|G^*|$ and δ.

Table 3.3: Binder performance grade and content of the laboratory prepared mixtures

Mixture	Performance grade (PG)	Binder content (%)
S1	58-28	5.5
S2	58-28	5.3
S3	52-28	6.5

3.4 Preparation of Test Specimens

3.4.1 Laboratory Compacted Specimens

The laboratory compacted specimens consists of those subjected to the axial compression $|E^*|$ test and the indirect tensile M_R and $|E^*|$ tests. All laboratory prepared mixtures, S1-S4 and B1-B4, were tested under the axial compression $|E^*|$ test while B2-B4 of these mixtures were subjected to indirect tensile testing to determine M_R.

The axial compression $|E^*|$ test specimens were prepared in according to AASHTO TP62-03 test method "Determining Dynamic Modulus of Hot-Mix Asphalt Concrete Mixtures". The specimens were prepared as follows:

1. Mixing an amount of aggregates and binder that is enough for one sample. The mix proportions are equal to those of the field mixture. The mixing temperature is 135°C.

2. Aging the mix for two hours in accordance with short-term oven aging procedure. The aging time is defined based on Manitoba practice considering the weather during the construction season and grade of the binder where Manitoba utilizes soft binder.

3. Compacting the mix with a gyratory compactor to obtain a 170 mm height specimen. The design number of gyrations (N_{des}) is 100 for S3 and B3 and 75 for the remaining mixtures.

4. Repeating steps 1 to 3 to generate three gyratory specimens. Table 3.4 lists the average volumetric properties of the gyratory samples prepared from each mixture. Figure 3.5 shows the densification curves of each mixture obtained during the compaction.

5. Extracting the test specimens from the centre of the gyratory specimens. First, core a 100 mm diameter specimens from the middle of the gyratory specimen and then cut equal amounts of the ends to obtain the test specimens with the nominal 150 mm height.

6. Checking the ends of the test specimens. The waviness height was checked for the target 0.05 mm using a feeler gauge and a straight edge. The specimen ends were checked to be perpendicular to the axis of the specimen with a mechanist square and feeler gauge.

7. Each test specimen was instrumented with three transducers to measure the axial deformation between gauge points 100 mm apart.

Table 3.4: Volumetric properties of the gyratory

Mixture	MTSG	Asphalt content (Ac) (%)	Asphalt Absorp. (%)	Bulk Density (kg/m3)	Air Voids (%)	VMA (%)	VFA (%)	P^a_{be} (%)

69

The indirect tensile specimens were prepared from B2-B4 with the gyratory compactor by following the steps 1 to 4 from the procedure of preparing the axial compression test specimens. Three gyratory specimens with 120 mm height were prepared from each mixture. Each gyratory specimen was sawed into two test specimens of 51 mm thick. Table 3.5 lists properties of the gyratory specimens made from B2-B4 for indirect tensile test specimens. Comparing Table 3.5 and Table 3.4 for B2-B4, the density of the gyratory specimens that have 170 mm height is slightly higher (up to 4% difference) than for the ones that have 120 mm height since the density depends on the compaction effort per unit of volume.

3.4.2 Field Compacted AC cores

The stored twelve whole field AC cores were split to layers to extract the test cores from the surface and binder courses. The test cores were prepared in accordance with the test protocol of the LTPP Project P07. Only three test cores from each layer were tested in the thesis test program. The other nine test cores were used to determine the indirect tension

strength of the material, to perform the volumetric analysis, and other three to substitute the damaged cores during the tests. Table 3.6 lists the properties of the test cores measured immediately after cutting. The properties consist of core height, bulk density, maximum theoretical specific gravity (MTSG) and in-place air voids.

[b]Maximum Theoretical Specific Gravity

The percents of RAP, if present, are known from history of the field mixes. The test cores have thicknesses in the range of 31 mm to 53 mm, which meets the LTPP P07 required

range of 25 to 51 mm. The bitumen extraction was performed after completing the mechanical tests carried on the test cores as shown by Figure 3.1. Table 3.7 lists the binder contents and rheology of the extracted binder and Figure 3.5 illustrates the gradations of the recovered aggregates. The recovered aggregates of all mixtures have NMPS of 12.5 mm.

3.5 Test Setup

Figure 3.7 shows the test setup used to carry out the test program including axial compression and indirect tensile testing. It consists of the following equipment and instruments:

a. A closed-loop servo-hydraulic testing machine. The capacity of the loading frame is 25 kN. The machine is capable of applying cyclic and static loads and can be adjusted to work under load or deformation control modes.

b. Load cell to measure the applied load, the cell was mounted on the stroke bar to measure the applied load.

c. Deformation measuring systems: two systems were calibrated and used in the test

program.

    i.   Linear Variable Displacement Transducer (LVDT), model Trans-TEK 0350-0010 with mechanical travel 3.5 mm (0.14 in) and internal carrier frequency greater than 1300 HZ.

    ii.   Extensometers with a 0.5 mm mechanical travel, model Epsilon 3910, with 4 inch axial conversion.

  d. Controller to generate the loading waveform.
Figure 3.7: Test setup of the laboratory testing

d. Environmental chamber to condition and control the test specimens at the desired test temperatures. The chamber uses liquid nitrogen to condition the specimens at temperatures less than the room temperature, while high temperatures are generated by an electrical heating element.

e. Data acquisition system (DAQ) to capture the applied load and the specimen deformations. Nine data channels were acquired at a time consisting load, stroke bar movement, four extensometers and three LVDTs.

f. A dummy specimen with a thermocouple embedded in its middle to monitor the equilibrium temperature of the test specimens. The dummy specimen has dimensions equal to the dimensions of the $|E^*|$ specimens.

g. Loading plates: in the axial compression $|E^*|$ test, the load was transmitted via two circular plates to the specimen while, in IDT testing, the load was transmitted to the specimen with two 38 mm wide curved plates with curvature of 150 mm.

3.6 Specimen Instrumentation

Two specimen instrumentation methods were used in the test program for the axial compression $|E^*|$ testing and IDT testing. Figure 3.8 shows the instrumentation of the axial compression $|E^*|$ test specimen. The axial deformations were measured with LVDTs or extensometers at three locations on the specimen surface located 120° apart. The axial deformations were measured between gauge points glued to the specimen and located vertically at both ends of a gauge length (L_g) of 100 mm. LVDTs were mounted onto the gauge points with screws but the extensometers were mounted using a magnetic base.
Figure 3.8: Specimen and instrumentation of the dynamic modulus test

(a) Extensometers, and (b)LVDTs

An end friction reducer (EFR) was used between the specimen and the circular loading plates. EFR consisted of two latex sheets filled with silicone grease. $|E^*|$ and ϕ measured using LVDTs and extensometers were compared, the results were documented in Appendix B. There was no significant difference between $|E^*|$ and ϕ obtained with the two instrumentations of the axial $|E^*|$ test. On the other hand, Figure 3.9 presents the specimen instrumentation of the IDT testing to measure M_R and the indirect tensile $|E^*|$. The load was transmitted to the specimen along the diameter via curved strips. The deformations were measured using four extensometers mounted on gauge points located 38 mm apart on the horizontal and vertical axis of the two specimen ends.
Figure 3.9: specimen and instrumentation of the indirect tensile testing

3.7 Procedure of Dynamic Modulus Test

The $|E^*|$ test was carried out in accordance with AASHTO TP 62-03 at four temperatures, -10, 5, 25 and 40°C, and six loading frequencies, 25, 10, 5, 1, 0.5 and 0.1 Hz, at each temperature. The tests proceeded from low to high temperature. At a given temperature, the testing began with high loading frequency and proceeded to low loading frequency. At each combination of temperature and frequency, the specimen was subjected to cyclic sinusoidal loads at a stress level adjusted to maintain axial resilient deformation within a range of 50 to 150 microstrains. The cumulative permanent deformation should not exceed 1500 microstrains at the end of a frequency sweep test at each temperature. The test procedure was as follows:

a. Conditioning the instrumented specimens in the environmental chamber at the given temperature. The temperature inside of the specimens was checked with the dummy specimen and the thermocouple.

b. Adjusting the LVDT to near the end of its linear range to allow the full range to be available for the accumulation of compressive permanent deformation.

c. Applying a contact load of 5 % of the cyclic load.

d. Adjusting and balancing the electronic measuring system as necessary.

e. At each temperature, the specimen is preconditioned first with 200 cycles at 25 Hz. Then specimen is loaded as specified in Table 3.8.

f. At each temperature, the test was carried at the highest frequency (25 Hz) and then proceeded to the lowest frequency (0.1 Hz).

g. Allowing at least 2 minutes rest period between testing between each of two

subsequent frequencies but not exceeding 30 minutes.

h. Repeating the test at the higher temperature with the same procedures a-g above.

Table 3.8: Number of applied load cycles at each test frequency

Frequency (Hz)	Number of Cycles
25	200
10	200
5	100
1	20
0.5	15
0.1	15

3.8 Test Measurements

The load- and deformation- time history of $|E^*|$ testing was collected in arrays consisting of the time, load, actuator position and the axial deformations at three positions. Table 3.9 lists the sampling rate of the collected data of $|E^*|$ test. The last five load cycles of each test were processed to determine the $|E^*|$ and ϕ. Figures 3.10 and 3.11 present a sample of the applied load and the resulting deformation at one transducer obtained at low and high temperatures, respectively.

Table 3.9: Data sampling rate of the dynamic modulus test

Frequency (Hz)	Sampling Rate (point/sec)
25, 10	1000
5, 1	500
0.5, 0.1	250
Figure 3.10: Typical load and deformation at low temperature (-10°C)
Figure 3.11: Typical load and deformation at high temperature (40°C)

The regression technique was used to smooth the measured data. Equations 3.1 and 3.2 were used to fit the load and deformation data, respectively.

$$P = P_0 + P_1 t + P_2 \cos(2\pi f t + \phi_P)$$

(3.1)

$$D = D_0 + D_1 t + D_2 \cos(2\pi f t + \phi_D)$$

(3.2)

where:

P and D = load and deformation respectively

t and f = time (s) and frequency (Hz).

$P_0, P_1, P_2, D_0, D_1, D_2, \phi_P, \phi_D$ = regression constants.

The cyclic stress applied on a specimen is obtained from Equation 3.3.

$$\hat{\sigma} = \frac{2P_2}{A}$$

(3.3)

where

A = cross section area of the specimen.

The recoverable strain at each transducer is obtained from Equation 3.4.

$$\hat{\varepsilon} = \frac{2D_2}{L_g}$$

(3.4)

$|E^*|$ at a transducer is calculated from the stress and strain by applying Equation 2.11 and ϕ is calculated using Equation 3.5.

$$\phi = \frac{\phi_D - \phi_P}{\pi} \times 180$$

(3.5)

Appendix C consists of the following test results at each combination of temperature and frequency:

- peak stress of each specimen,

83

- strain, $|E^*|$ and ϕ lat each transducer on the test specimen

- $|E^*|$ and ϕ of each test specimen

- $|E^*|$ and ϕ of the mixture, the average, standard deviation and coefficient of variation of the three LVDT/Extensometer positions (within the specimen) and those of the three replicates.

3.9 Indirect Tensile Testing

Laboratory and field compacted specimens were tested in the indirect tensile mode to determine M_R and $|E^*|$. The laboratory compacted specimens of B2-B4 and the field AC cores except B2 and B3 were subjected to M_R and 100 s creep compliance tests in accordance with the LTPP project P07. The tests were performed at -10, 5, 25 and 40°C proceeding from lower to higher temperatures. The M_R was measured by applying 0.1s haversine pulse load followed by 0.9 s rest period, as shown in Figure 2.11. The test sequence for the laboratory compacted specimen is as follows:

1. At -10°C, creep compliance,

2. At 5°C, resilient modulus followed by creep compliance,

3. At 25°C, resilient modulus followed by creep compliance, and

4. At 40°C, resilient modulus.

In chapter 6, an approach is introduced to predict $|E^*|$ from M_R.

The laboratory compacted B2 and B3 were subjected to further testing to determine indirect tensile $|E^*|$ at temperatures 5, 25 and 40°C and eight loading frequencies, 25, 10,

84

5, 1, 0.5, 0.1, 0.05 and 0.01 Hz, at each temperature. The Poisson's ratio calculated from M_R measurements showed that specimens behave in the linear stage where the frequency is less than 0.5. The field AC cores of B2 and B3 were subjected at 5, 25, 40°C to determine the M_R and then determine the $|E^*|$ at 25, 10, 1, 0.1, 0.01 Hz. A rest period of at least 2 minute was applied between two subsequent tests. The cyclic load was adjusted to maintain horizontal displacements between the gauge points to be less than 0.038 mm.

A Matlab code was developed based on an algorithm presented in LTPP P07 protocol "Test Method for Determining the Creep Compliance, Resilient Modulus and Strength of Asphalt Materials Using the Indirect Tensile Test Device". The raw data was processed using this code to obtain the instantaneous and total displacements, which were used to obtain instantaneous and total M_R and the Poisson Ratio.

4 Dynamic Modulus of Asphalt Concrete: Test Methods and Prediction Models

4.1 Introduction

Laboratory testing and predictive models are the two methods of determining $|E^*|$ of asphalt concrete. The aim of this chapter is to evaluate these methods for asphalt mixtures containing local aggregates and soft asphalt binders such as ones used in Manitoba, Canada and similar cold regions. $|E^*|$ and ϕ are evaluated in terms of the variability. The shifting methods for developing $|E^*|$ master curve from the measured $|E^*|$ are compared. The prediction accuracy of the Witczak $|E^*|$ model was assessed and the impact on the predicted pavement performance was examined.

4.2 Variability of Laboratory Measured Complex Modulus

The variability was measured with the standard error (S_e) calculated from between specimen and within specimen variabilities, Equation (2.20). Figures 4.1 and 4.2 show the average of S_e at each temperature calculated at the six loading frequency. Generally, the variability is more pronounced in $|E^*|$ than in ϕ especially at high service temperatures. The acceptance level of S_e of $|E^*|$ and ϕ is defined by AASHTO TP62-03 to be 15%. $|E^*|$ and ϕ of the mixtures except of those of B1 and B2 have limit of accuracy less than the acceptance level. $|E^*|$ of B1 and B2 has limits of accuracy that is slightly higher than 15 % at -10, 5°C. B1 and B2 contain high ratio of RAP and that may have increased the variability of $|E^*|$.

(a)
(b)

Figure 4.2: Standard error (S_e) of the phase angle within mixtures

(a)S1-S4. (b) B1-B4

Figure 4.3 shows the effect of test temperature on the variability in term of S_e of $|E^*|$ and ϕ between mixtures. S_e decreases with temperature and its decrease is more prominent in S_e of ϕ than in S_e of $|E^*|$. In addition to the variability in the measured data, the consistency of $|E^*|$ test data can be used to examine the data quality. Figures 4.4 and 4.5 show consistency of $|E^*|$ and ϕ illustrated by the complex plane (Cole-Cole) and the black space as explained in section 2.5.3.

(b)

Figure 4.5: Black space, phase angle versus dynamic modulus

(a) Surface mixtures. (b) Binder mixtures

$|E^*|$ and ϕ at various temperatures and frequencies are consistent since the values are fitted by smooth curves in the black space at high stiffness and the complex plane at low stiffness. The black space and the complex plane can be used to compare $|E^*|$ and ϕ of specific mixtures measured by different testing methods since they do not depend on the test conditions.

4.3 Isothermal and Isochronal Curves of $|E^*|$ and ϕ

The $|E^*|$ and ϕ depend on two parameters: temperature and loading frequency. They are represented graphically by the isothermal and isochronal curves, Figures 4.6 and 4.7 respectively. The curves were used to find the deviated value from average data trends. They also illustrate the relationship between the measured data and the test conditions, temperature and frequency. They are simple ways to understand the effect of traffic speed and pavement temperature on AC stiffness since a constant design speed is allowed for a given highway. For a constant traffic speed, stiffness is best represented with the isochronal curve. The following observation are made:

- In general, isothermal and isochronal curves generated from $|E^*|$ data are more consistent than those curves generated from ϕ data.

- At a given temperature, $|E^*|$ increases with frequency while it decreases with temperature at a given frequency. The frequency has a large effect at high temperature than low temperature.

- On the contrary, ϕ decreases with frequency at low temperatures (-10 and 5°C).

92
(a)
(b)

Figure 4.6: Isothermal curves for S1 mixture

(a) Dynamic modulus, (b) Phase angle

93
(a)
Figure 4.7: Isochronal curves for S1 mixture

a) Dynamic modulus, b) Phase angle

- At higher temperatures (25 and 40°C), the relationship between ϕ and frequency is not consistent. At 40°C, the phase angle is not sensitive to the loading frequency. The effect of aggregate on the rheology of mixtures increases in comparison with the effect of binder. Response (Kim and Lee 1996).

4.4 Evaluation of Shifting Techniques

Figure 4.8 illustrates the influence of the shift function on developing the $|E^*|$ master curve from measured $|E^*|$. Five techniques that are introduced in Section 2.4 are compared. The coefficients of the sigmoidal function, δ, α, β, γ, and shift factors have been obtained simultaneously by applying a non-linear fitting technique to minimize the sum of squared errors between the measured and fitted $|E^*|$. Figure 4.8 shows that different $|E^*|$ master curves at a reference temperature of 25°C have been obtained when different shift functions are applied producing different estimated $|E^*|$ and reduced frequency. It is important to note that the master curve should be analyzed with its associate shift function. For a reasonable visual comparison between AC mixtures using the master curve, it is preferable to use the same shift function for mixtures under comparison.

Table 4.1 lists the coefficients of master curves and shift factors that were obtained with the experimental method. These shift factors vary from mix to mix. Since they were obtained without constraints other than the minimum value of sum squared errors between measured $|E^*|$ and fitted $|E^*|$, they may be sensitive to the change in the testing program, for example testing at other temperatures and frequencies. Different shift factors of mixtures at a given temperature result in different reduced frequencies for a given loading frequency.
Figure 4.8: The master curve of S1 using the five shift functions

The shift functions have been examined using S1-S4 and B1-B4 to select a function that is less sensitive to mixture property. The coefficients of the shift functions, Equations (2.15 to 2.19), have been determined simultaneously with coefficients of the master curves for each mixture. Table 4.2 lists the viscosity-temperature susceptibility parameters, A and VTS, of the binders obtained from the complex shear modulus (G^*) and the phase angle (δ). These values have been used to generate the A-VTS shift function.

Table 4.1: Coefficients of $|E^*|$ master curves and shift factors of mixtures

Mixtures	Coefficients of $|E^*|$ master curves				Shift factor , Log $a(T)$		
	δ	α	β	γ	-10°C	5°C	40°C
S1	1.374	3.232	-0.264	0.547	4.234	2.242	-1.409
S2	1.549	3.054	-0.156	0.530	4.328	2.187	-1.304
S3	1.697	2.830	-0.778	0.534	4.007	2.187	-1.516

B1	1.206	3.301	-0.514	0.494	4.176	2.392	-1.321
B2	1.500	3.002	-0.701	0.457	4.735	2.291	-1.423
B3	1.579	2.706	-0.371	0.539	4.185	2.122	-1.227
B4	0.597	3.909	-0.502	0.415	4.418	2.021	-1.113

Reference temperature = 25°C,

Table 4.3 lists statistics, the maximum value, the minimum value and the coefficient of variation (CV), of the coefficients of shift functions. These values have been obtained from the calculated coefficients of all mixtures. The activation energy (ΔE_a) is less sensitive to mixtures as shown by low CV. On the contrary, coefficients of WLF shift function are sensitive to the mixture property where CV is 25% for C1 and 21% for C2. Coefficients of Log linear and A-VTS functions have moderate sensitivity to mixtures.

Based on this comparison, the Arrhenius function with ΔE_a of 175 KJ/mol is recommended to construct the master curves of these mixtures for estimation of $|E^*|$ and for the visual comparison using the master curves of mixtures. Figure 4.9 presents the goodness of fit (S_e/S_y) of the master curves constructed using the five shift functions. The goodness of fit is the ratio of the standard error of the $|E^*|$ obtained from the master curve to the standard deviation of the measured $|E^*|$. The higher the S_e/S_y value is, the lower accuracy of the fitted master curve.

Table 4.2: Performance binder grades and parameters of viscosity-temperature susceptibility

Mixture	Binder grade (PG) .	A	VTS

Se/Sy of the master curves

Sample size = 8

Experimental   Log-linear   WLF   Arrhenius   A-VTS
The shift function

Figure 4.9: Goodness-of-fit of $|E^*|$ master curves using shift functions

The experimental shifting technique produces the most accurate master curves. On the contrary, Log-linear shift function produced the least accurate fitted master curves. The $|E^*|$ fitting errors were investigated at the test temperatures, Figure 4.10. The error increases slightly with temperature. The 10% of the sample at 25°C has errors up to 30%. This behaviour at 25 C, which is the reference temperature, can be explained by constraining the value of the shift factor at this temperature. All shift functions can reasonably be used to construct the $|E^*|$ master curves except the log-linear function where the error was within ± 20% at -10 and 25°C. The fitting errors produced by applying the experimental method and WLF function were within ± 10%, increase with temperature and are normally distributed since the median error is zero.
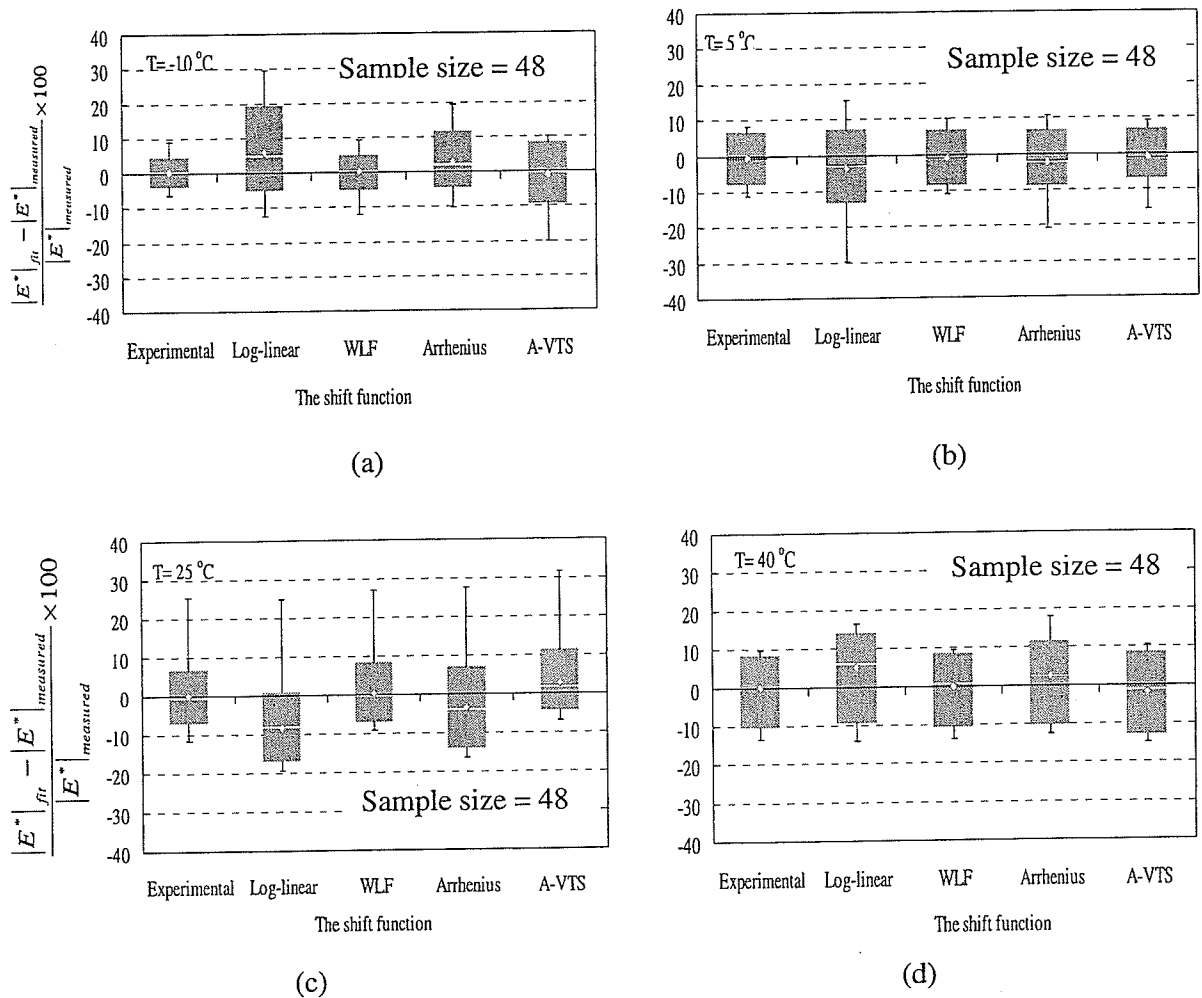

Figure 4.10: Distribution of $|E^*|$ fitting error of the master curves at temperatures

(a)-10°C, (b) 5°C, (c) 25°C, and 40°C

A-VTS function can be used to obtain the shift factors from properties of binders allowing the rheology of binders to be incorporated. Although the WLF function produces small fitting errors and low S_e/S_y comparing to the other functions, the Arrhenius and A-VTS functions are recommended for constructing master curves because their constants are less sensitive, low CV, to the properties of the mixtures.

4.5 Evaluation of Witczak $|E^*|$ Prediction model

The Witczak $|E^*|$ model, Equation 2.49, was used to predict $|E^*|$ of S1-S4 and B3-B4 from the mixtures volumetric properties. Table 4.4(a) lists aggregate gradation parameters and volumetric properties of mixtures required to predict the modulus using the Witczak model at design level 2 and 3. At design level 2, the viscosity (η) of the binders was estimated from the DSR parameters measured at angular velocity (ω) of 10 rad/sec and temperature range from 7 to 70°C. The viscosity-temperature susceptibility model, Equation (2.20) was applied for each binder grade to obtain A and VTS to be used to calculate the viscosity at any temperature. Table 4.2 lists A and VTS obtained from the measured G^* and δ. At design level 3, where no laboratory measurements for the binder are required, typical values of A and VTS of a given binder grade can be obtained from NCHRP (2004). Table 4.4(b) lists the typical A and VTS for binder grades used in S1-S4 and B3 and B4 mixtures.

Figure 4.11 shows the comparison of the predicted and measured $|E^*|$ master curves of S1-S4 and B3 and B4 mixtures at the design levels 2 and 3. Generally, the Witczak model characterized the effect of the loading time quite well but it overpredicts $|E^*|$ especially at low stiffness/high temperatures. It is noticed that the prediction errors at design level 3 is slightly lower than those at level 2 for S1 to S3 while the opposite is true for the remaining mixtures. The higher reliability of the $|E^*|$ prediction does not guarantee low errors. For representative measurements, $|E^*|$ should be obtained from direct testing or high reliable prediction techniques.

At level 2 and 3, the predicted errors at low temperatures (-10 and 5°C) are lower than those at high temperatures. The predicted values for S1-S4 range from -0.65 to 2.5 times those

measured in the laboratory at intermediate and high temperatures (25 and 40°C). The prediction errors for B3-B4 range from -0.3 to 1.5 times of the measured $|E^*|$. $|E^*|$ at high temperature correlates significantly with the permanent deformation and rutting (Witczak et al. 2002a). Figures 4.12 and 4.13 show the distribution of the $|E^*|$ prediction errors at various measured $|E^*|$ values of S1-S4 and B3-B4 respectively.

Table 4.4(a): Inputs of the Witczak $|E^*|$ model of mixture properties, design level 2 and 3.

4.6 Impact of $|E^*|$ prediction error

The significance of $|E^*|$ prediction errors is best evaluated with their impact on the predicted pavement performance and the mixture comparison. A pavement cross section has been analysed to evaluate the impact of the prediction errors on the predicted pavement performance.

The $|E^*|$ errors of the mixtures tested in this study have almost the same pattern. At high stiffness/low temperatures, the errors are small in comparison to the errors at low stiffness/high temperatures. Neglecting the error at the high stiffness, the predicted $|E^*|$ of this pattern at various prediction levels of error at high temperature can be represented numerically using the sigmoidal function, Equation (2.22), by changing the minimum $|E^*|$ value while holding constant the maximum $|E^*|$ value in the following modified sigmoidal function.

$$\log\left|E^*\right| = \log\left|E^*\right|_{min} + \frac{\log\left|E^*\right|_{max} - \log\left|E^*\right|_{min}}{1 - e^{\alpha - \gamma \log(f_r)}} \qquad (4.1)$$

where

$\left|E^*\right|_{min}$: minimum dynamic modulus of a mixture,

$\left|E^*\right|_{max}$: maximum dynamic modulus

Comparing with Equation 2.22, it can be noticed that

$\delta = \log\left|E^*\right|_{min}$ and

$\delta + \alpha = \log\left|E^*\right|_{max}$

The maximum $|E^*|$ and the minimum $|E^*|$ values obtained from δ and α depend not only on the mixture property but also on the $|E^*|$ test conditions, temperature and frequency; therefore

they are not pure material properties. Figure 4.14 shows $|E^*|$ master curves generated from coefficients from S1, shown in Table 4.1, with changing δ to produce $|E^*|$ values at 40°C and 1Hz, $|E^*_{40}|$, that are 0.5, 1, 1.5, 2.0 and 3.0 times of the actual value of $|E^*_{40}|$.
Figure 4.14: $|E^*|$ master curves of S1 generated at various prediction errors at low stiffness

S1 is a surface asphalt mixture for PTH 8 located in Manitoba. The road is 4 lane divided highway. Based on 2005 traffic count at station number 1 that located 1.4 Km south of PR 321, the annual average daily traffic (AADT) of PTH 8 is 10900. The count station is classified as regular permanent count station (PCS) where no weight or vehicle classification data was collected. The assumed average annual daily truck traffic (AADTT) is 2000, which

is about 18% of AADT, and it contains mainly class 9 trucks. The percent of AADTT of 2005 traffic counts in Manitoba was up to 30% of AADT.

The cross section consists of subgrade classified as A-6 AASHTO soil with stiffness of 100 MPa, a 500 mm base course from crushed gravel with stiffness of 170 MPa, and 200 mm asphalt concrete. The thickness of the asphalt layer constructed from S1 was determined using the MEPDG software of NCHRP project 1-37A to support the AADTT with annual growth of 2% and design service life of 20 years. The default design criteria of fatigue and rutting at a reliability level of 90% were applied. The criteria were 25% fatigue cracking, 6 mm asphalt layer rutting and 18 mm total rutting.

Figure 4.15 shows the predicted pavement performance, rutting, fatigue cracking and longitudinal cracking, over a design life. The rutting of the asphalt layer and total rutting of pavement are 7 and 19 mm respectively and the maximum fatigue cracking is 25%.

Sensitivity of the predicted pavement performance to the variation in $|E^*|$ at high temperature has been examined. Figure 4.16 shows the sensitivity of rutting and fatigue cracking. Although the pavement cross section lies in a cold region, the cold temperature distresses has been excluded from the sensitivity analysis since its model does not depend directly on $|E^*|$. The predicted pavement performance is sensitive to the variation of $|E^*|$ at low stiffness/high temperatures and overprediction of $|E^*|$ leads to underestimate the pavement performance and unconservative pavement design.
(a)
(b)
(c)

Figure 4.15: The predicted pavement performance:

(a) Rutting, (b) Fatigue cracking, c) Longitudinal cracking

111

For the given pavement section, the $|E^*|$ variation has an identical effect on the fatigue cracking and total rutting. It was noticed that the effect on rutting of asphalt concrete is higher than the effect on total rutting. Underpredicting $|E^*|$ by 50% overestimates the total rutting, fatigue cracking, AC rutting and longitudinal cracking by 20%, 20%, 30%, 70% respectively. Overpredicting $|E^*|$ by 250% underestimates the total rutting, fatigue cracking, AC rutting and longitudinal cracking by 25%, 25%, 40% and 100% respectively.
Figure 4.16: Sensitivity of the pavement performance to AC stiffness

4.7 Summary

The chapter evaluates the determination of $|E^*|$ of AC mixtures used in Manitoba and similar cold regions. The variability in $|E^*|$ and ϕ has been evaluated within a mixture and at the test

temperatures. The shift techniques applied to develop $|E^*|$ from measurements have been compared. The prediction of $|E^*|$ from the volumetric properties has been carried out using the Witczak model and the impact of prediction errors on the pavement performance have been evaluated.

The variability of $|E^*|$ within a mixture does not change significantly from a mixture to another and with test conditions. Therefore the variability of $|E^*|$ may be used to examine the variability in AC. The Arrhenius' function has been recommended as a shift factor function to develop master curves when the experimental method can not be applied and a visual comparison between mixtures is required (Pellinen et al., 2004). The Witczak model overpredicts $|E^*|$ at high temperature and the prediction error has a significant impact on the pavement performance.

5 Improving the Prediction of the Dynamic Modulus of Fine-Graded Asphalt Concrete Mixtures at High Temperatures

5.1 Introduction

A linear model is developed to predict $|E^*|$ at 40°C using a gradation parameter. The model is used to improve the reliability in the prediction of $|E^*|$ at high temperatures and to adjust the $|E^*|$ master curve constructed using the Witczak $|E^*|$ predictive model. The approach presented in this chapter was presented in Harran and Shalaby (2009).

5.2 Dynamic Modulus-Gradation Relationship

The relationship between $|E^*|$ at high temperature and aggregate gradations is examined using the following gradation parameters: the percent passing the 0.075 mm sieve, the percent passing the 4.75 mm sieve and a gradation ratio (GR). The gradation ratio is proposed in the thesis and can be defined as follow:

$$GR = \frac{\% \text{ Passing } 4.75 \text{ mm sieve}}{\% \text{ Passing } 0.075 \text{ mm sieve}} \qquad (5.1)$$

The 4.75 mm sieve and the 0.075 mm sieve are selected since they are typically used to split the aggregate into three portions, coarse aggregate (CA), fine aggregate (FA) and mineral filler. GR measures the ratio of the FA portion to the mineral filler portion. The

dynamic modulus at 40°C and 1 Hz, $|E_{40}^*|$, is selected to capture the influence of the aggregate gradation (Birgisson and Roque, 2005). A statistical analysis is carried out to test the relationship between $|E_{40}^*|$ and the gradation parameters at a threshold significance level (ρ) of 0.05.

The analysis is conducted using four mixture groups that included a total of 24 mixtures, Table 5.1. Table 5.2 lists properties of the mixtures that are used to study the relationship between the gradation parameters and the dynamic modulus at high 40°C. The first group, G1, consisted of six mixtures, S1-S4, B3 and B4. B1 and B2 are not considered because they contain percents of RAP. More information about S1-S4 and B1-B4 can be found in chapter 3. The second group, G2, consists of 6 fine-graded mixtures and the third group, G3, consists of 7 coarse-graded mixtures.

Table 5.1: Characteristics of the mixture groups

Mixture group	Mixture source	Aggregate classification	Number of mixtures	Binder grade
G1	University of Manitoba	Fine-graded	6	PG58-28, PG 52-28 PG 58-34
G2	Florida	Fine-graded	6	PG 67-22 (AC- 30)

[a]Interpolated value using measured dynamic moduli at 37.8°C and 54.4°C,

The G2 and G3 mixtures were used in a project at the University of Florida to develop the gradation-based mixture design guideline that is described in section 2.6.5. They consisted of laboratory and field mixtures containing limestone and granite aggregates and a single binder grade of PG 67-22. G2 and G3 were prepared based on the SuperPave mix design. Additional information about these mixtures can be found in Birgisson and Roque (2005). The available information included volumetric properties and dynamic modulus at $40^{\circ}C$ and 1 Hz, $|E_{40}^{*}|$.

The fourth group, G4, is used to validate the proposed model. It consists of the five mixtures of the Minnesota Road research project (MnRoad) experimental test site, cells 16-18, 20 and 22, as reported by Pellinen (2001). The MnRoad mixtures were prepared from materials sampled from the experimental test site and contained various aggregate gradations and two binder grades. Cells 16-18 contained an AC-20 binder while cells 20 and 22 contained a 120-150 penetration grade binder. A SuperPave gyratory compactor was used to duplicate the field-compacted mixture properties. G4 mixtures were prepared according to the Marshall mix design except for cell 16 mixture which was designed according to the SuperPave mix design.

The dynamic modulus-aggregate gradation relationship is tested within five dataset groups, G1, G2, (G1 and G2), G3 and (G2 and G3). The first three datasets are fine-graded mixtures. The G1 and (G1 and G2) contain various binder grades to test the relation in mixtures that include different binder grades. The G2, G3 and (G2 and G3) contain a single binder grade, PG 76-22, as such the effect of the binder rheology on the

relationship is neutralized. The fourth dataset, G3, contains coarse-graded mixtures and the fifth dataset, (G2 and G3), contains combined fine- and coarse-graded mixtures. The relationship is tested at two sample size levels of the fine-graded mixtures that include various binder grades. The G1 dataset has a sample size of 6 and a GR range of 12.3-17.7 and the (G1 and G2) has a sample size of 12 and a GR range of 9.7-17.7. The relationship is considered significant if the correlation coefficient (r) is higher than or equals the critical correlation coefficient (r_{crt}) at a significance level of 0.05 or less.

Table 5.3(a) lists the correlation coefficients between $|E_{40}^*|$ and the gradation parameters. The data shows that the GR has the potential to describe the relationship between $|E_{40}^*|$ and aggregate gradation. Table 5.3(b) summarizes the relationship between GR and $|E_{40}^*|$ in the various datasets, G1, G2, (G1 and G2), G3, and (G2 and G3).

The following observations can be made for the relationship between the GR and $|E_{40}^*|$:

- In fine-graded mixtures, the relationship is significant regardless of the binder grade.

- The relationship is not significant in coarse-graded mixtures.

- The relationship is also not significant in the combination of coarse-graded and fine-graded mixtures.

For the fine-graded aggregates, G1 and G2, the correlation between $|E_{40}^*|$ and the asphalt binder content, the effective volume binder content (V_{eff}), the air voids (V_a) and the voids in mineral aggregates has shown weak correlations where it was found 0.25, –0.20, –0.29 and –0.54 respectively

118

Table 5.3(a): Correlation coefficients (r) between $|E_{40}^*|$ and aggregate gradation parameters

Significant ($\rho \leq 0.05$)	Yes	Yes	Yes	No	No

5.3 $|E_{40}^*|$-GR Regression Model

Figure 5.1 shows the relationship between $|E_{40}^*|$ and GR for both fine-graded and coarse-graded mixtures respectively. Figure 5.1(a) shows the 95% confidence limits based on G1 and G2 datasets and suggests a linear relationship for fine-graded mixtures. The confidence limits suggest that S3 data point is an outlier.

(a)

(b)
Figure 5.1: Dynamic modulus at high temperature versus the gradation ratio (GR)

(a) Fine-graded mixtures. (b) Coarse-graded mixtures.

It can be noticed that $|E^*_{40}|$ of S3 is relatively high compared to $|E^*_{40}|$ of G1 and G2 mixtures that have similar GR values. Accordingly, S3 data was excluded from the regression model. The model, as shown by Equation 5.2, was found to be statistically significant for the range of GR values of 9.7 to 17.7.

$$|E^*_{40}| = -87\,(GR) + 1926 \tag{5.2}$$

where

$|E^*_{40}|$ = the dynamic modulus at 40°C and 1 Hz, in MPa

The statistics of the model shown by Equation (5.2) is as follows:

N = 11 (based on G1 and G2 mixtures, S3 excluded)

$r^2 = 0.89$, the adjusted $r^2 = 0.87$

S_e = the standard error of estimate = 93.00 MPa

S_y = the standard deviation = 265.00 MPa

$S_e/S_y = 0.35$ and $\rho = 0.00001 < 0.05$

The statistics of the model confirm a significant relationship between $|E^*_{40}|$ and GR for fine-graded mixtures. The data consists of 11 fine-graded mixtures with different aggregate gradations, aggregate sources, and binder grades. The aggregates passing both the 0.075 mm and the 4.75 mm sieves are in the range of 3.5% –6.3% and 61.3% –77.5% respectively. The model is simple since it includes one independent variable (GR) and it is rational since $|E^*_{40}|$ decreases as GR increases. Figure 5.1(b) shows the relationship between $|E^*_{40}|$ and GR in coarse-graded mixtures.

5.4 Validation of the $\left|E_{40}^*\right|$-GR Model

The model was validated with the datasets used for the calibration, G1 and G2, and with an independent dataset, G4. The validation with G1 and G2 illustrates the accuracy of the model when applied to its calibration data. Figure 5.2 shows the $\left|E_{40}^*\right|$ prediction errors of G1 and G2 using the proposed model shown by Equation (5.2) and the Witczak model. The proposed model predicts $\left|E_{40}^*\right|$ of G1 and G2 reasonably well where the prediction errors range between −32% and +20%. These prediction errors are much lower than those of the Witczak model, which were in the range of −50% and +210%. The comparison demonstrates the potential of using GR to adjust the predicted $|E^*|$ master curve generated by the Witczak model.

The predicted $\left|E_{40}^*\right|$ values of G1 with the Witczak model are obtained at design level 2 and level 3 and those of G2 are obtained at design level 3 only. The typical binder values, A and VTS, for design level 3 are provided by the MEPDG (NCHRP 2004). The Witczak model mostly tends to overpredict $\left|E_{40}^*\right|$ at the two reliability levels.

The proposed model is verified using the independent dataset, G4. Figure 5.3 shows the prediction errors of $\left|E_{40}^*\right|$ for G4. The $\left|E_{40}^*\right|$ values of G4 mixtures are interpolated using measured values at 37.8°C and 54.4°C (100°F and 130°F).The model predicted $\left|E_{40}^*\right|$ of four mixtures of G4 reasonably well with an error range of −34% to +21%, and over-predicted $\left|E_{40}^*\right|$ of Cell 20 by almost 90%. Cell 20 has low $\left|E_{40}^*\right|$ in comparison with the other G4 mixtures and that may result from the low compaction of its specimens.
(a)
(b)

Figure 5.2: Comparison of the prediction error in $|E^*_{40}|$ using the proposed and Witczak models (a) G1 and (b) G2.

Schwartz (2005) used the MnRoad mixtures, G4, to validate the Witczak model and reported $|E^*|$ prediction errors up to 350% at low stiffness/high temperatures. In comparison with the $|E^*|$ prediction by using the Witczak model, the GR model predicts $|E_{40}^*|$ reasonably well for the independent mixtures, G4, and the calibration mixtures, G1 and G2. It can be noticed that the effective binder content by volume and air voids of G4 mixtures are higher than those of mixtures used to calibrate the model. The aggregate gradation confirms being the most dominant property at high temperatures, and the differences in the binder rheology and the volumetric properties of mixtures have small effect on the predicted $|E_{40}^*|$.
Figure 5.3: Verification of the $|E_{40}^*|$-GR model using G4 mixtures

5.5 Effect of Reclaimed Asphalt Pavement on Gradation Ratio-Stiffness Relationship

Figure 5.4 shows the relationship between M_R at 40°C and GR for field compacted AC cores that were extracted immediately after construction. The data is from 17 field mixtures extracted from 4 surface and 13 binder courses as shown in Table 3.1. Six binder mixtures contain RAP with a range of 15% to 57% as shown in Table 3.6. It can be noticed that M_R at 40°C of S5 and B12 is not within the M_R range of mixtures that have the same GR values. The Poisson's ratio at 40°C of S5 calculated according to LTPP 07 project was a negative value so the test specimens may have experienced damage leading to unreasonable M_R value.
Figure 5.4: Effect of percent of reclaimed asphalt pavement on the relationship between aggregate gradation and stiffness of the mixture at 40°C

The low M_R value of B12 mixture may result from the high percent RAP in the mixture, which is 57%. Figure 5.4 confirms existing the relationship between the stiffness of fine-graded mixtures, which are represented with M_R or $|E^*|$, and the aggregate gradation represented with the proposed GR even in-service AC mixtures. Furthermore, it shows that RAP does not have a significant effect on the relationship.

5.6 Improving Witczak $|E^*|$ model at High Temperature

The model is used for adjusting the predicted $|E^*|$ master curve for fine-graded mixtures. The adjustment considers that the effect of aggregate gradation dominates $|E^*|$ at high temperature and this effect diminishes with decreasing temperature. The adjustment is performed in three steps. Firstly, the Witczak model is used to predict $|E^*|$ master curve using the volumetric properties of mixtures. Secondly, $|E^*_{40}|$ is predicted from the GR by applying the proposed model shown by Equation (5.2). Finally, the predicted $|E^*|$ master curve is pivoted at the highest reduced frequency ($f_r \approx 10^6$ Hz) and rotated to match the predicted $|E^*_{40}|$. Figure 5.5 illustrates the process of adjusting the predicted $|E^*|$ master curve of S1 and it compares the predicted $|E^*|$ master curves before and after the adjustment with the measured $|E^*|$ master curve. As illustrated in Figure 5.6, the predicted $|E^*|$ is improved at high and intermediate temperatures. Consequently, the predictions of rutting and fatigue cracking, which are relevant to the response at high and intermediate temperatures, are expected to be predicted more reliably. In addition, the model could be used as a preliminary mix design tool for optimizing stiffness of asphalt mixtures at high temperatures and accordingly reducing the potential of rutting. Higher stiffness mixtures can be achieved by lowering the GR.
Figure 5.5: Adjusting of the Witczak predicted $|E^*|$ master curve using the $|E_{40}^*|$-GR model.
Figure 5.6: the Witczak $|E^*|$ master curve before and after adjusting with the $\left|E^*_{40}\right|$-GR

mode

5.7 Discussion

The statistical analysis confirmed that aggregate gradation has a significant effect on the stiffness of asphalt concrete at high temperature and that GR appears to capture this effect adequately for fine-graded mixtures. This finding was validated in a relatively wide range of mixtures and aggregate blends. In mix design, a low GR should be desirable whenever possible, because it relates to a higher dynamic modulus. By definition, a lower GR is the result of a larger coarse fraction and a smaller fine fraction. A mixture with a low GR should have a higher percentage of interparticle contacts and crush counts than a mixture with a high GR.

These findings are consistent with the current mixture design practices which encourage stone-on-stone contact and better aggregate interlock with emphasis on aggregate shape and angularity. Excessive use of fines reduces the stiffness of the mixture and its ability to recover during unloading, thus leading to a more rapid rate of permanent deformations.

The Witczak model accounts for many aggregate, binder, and mixture properties and predicts performance reasonably well at low and intermediate temperatures; however at high temperature performance depends largely on the aggregate structure particularly with the soften types of asphalt used in cold regions. Using Witczak's model alone reduces the reliability of the modulus data at high temperature because the effect of aggregate structure may not be adequately represented in the model. The GR model, being statistically based on the GR and on laboratory tests performed at high temperature, can be used successfully to calibrate master curves produced by the more complex predictive models of dynamic modulus.

6 Pulse Time-Test Frequency Conversion Method

6.1 Introduction

Frequency (*f*) represents the time-dependent behaviour of AC under harmonic sinusoidal loading. On the other hand, pulse time (t_p) is the duration of the influence of the field or laboratory stress. In this chapter, an approach is proposed to convert the pulse time to frequency. The conversion method is required to assign $|E^*|$ as quasi-elastic AC modulus in the multilayered pavement system analysis, and to define the relationship between $|E^*|$ and AC stiffness under other loading forms. The approach is based on the viscoelastic theory and on equal recoverable strains resulting from both the pulse and sinusoidal stresses.

The field and laboratory pulse stresses can be represented with one of the symmetric shape forms listed in Table 2.1. In fact, the actual field stress shows delayed responses and has residual stresses due to the viscoelastic property (Al-Qadi et al., 2008b). The form of the field stress is best obtained from the analysis of the viscoelastic pavement system or measured directly from the field. Al-Qadi et al. (2002) found that the normalized bell-shape function shown by Equation (2.42) represents the measured vertical stress at various depths particularly for the loading side of the stress history. The difference between the field and laboratory stresses is that the rest period observed between load applications in the field is much greater than the rest period in the laboratory (Lytton et al., 1993). Consequently, almost all of the viscoelastic strain in the

130

field is recovered while the amount of recoverable resilient strain (ε_r) in laboratory tests depends on duration of the rest period. In this chapter, the equivalent frequency has been calculated for the loading pulse of the resilient modulus test by considering the instantaneous response.

In order to validate this method, $|E^*|$ and M_R are computed from the strains resulting from normalized continuous and pulse sinusoidal stresses, respectively. The results of the approach are compared with other methods from the literature.

6.2 Approach of the Pulse Time -Frequency Conversion

Figure 6.1 presents the proposed approach to calculate the test frequency of $|E^*|$ for a given normalized pulse stress. The controlling condition of the computation is that the recoverable strain (ε_0) of AC subjected to a normalized sinusoidal stress ($\sigma_0 = 1$) with f (Hz) is equal to the resilient pulse strain (ε_r) resulting from the normalized pulse stress. The ε_r for the field loading is assumed the maximum value of the strain history resulting from the normalized pulse stress. However, for the laboratory pulse loading, ε_r can be obtained from the strain history by applying definition of the resilient deformation, which is the instantaneous and total deformations, obtained from laboratory deformation plots.

The approach utilizes the linear viscoelastic theory represented by Equation (2.6) to determine the axial strain history, $\varepsilon(t)$, of AC subjected to an axial normalized pulse stress history, $\sigma(t)$.

| AC inputs: Creep compliance D_0, D_1 and m | | A normalized pulse stress with loading time (t_p) $\sigma(i\Delta t)$, where $0 \le i \le n$, Δt = time interval, and $n = t_p/\Delta t$ |

Calculating strain history; $\varepsilon(t)$
$$\varepsilon(k\Delta t) = D_0 \sigma(k\Delta t) + \sum_{i=0}^{k} D_1 \left(\Delta t(k-i)\right)^m (\Delta \sigma_i)$$
where: $0 \le k \le n$

Computing resilient strain, ε_r:
• For field loading:
$$\varepsilon_r = \max[\varepsilon(t)]$$
• For laboratory loading:
ε_r = instantaneous strain (ε_i)

Let:
Recoverable strain (ε_0) from a normalized sinusoidal stress = ε_r

Calculating $|E^*|(f)$ as follows
1. $D'(f)$; Equation (2.33)
2. $D''(f)$; Equation (2.34)
3. E' and E''; Equation (2.30)
4. $|E^*|(f)$; Equation (2.11)

Determining $|E^*|$
$$\left|E^*\right| = \frac{\sigma_0}{\varepsilon_0}; \; \sigma_0 = 1$$

Solving for frequency of $|E^*|$

Loading frequency (Hz)

Figure 6.1: Proposed approach to determine the frequency equivalent to a pulse time

132

AC is characterized with GPL creep compliance parameters, D_0, D_1 and m, as shown by Equation (2.4). The integration shown by Equation (2.6) is carried out numerically and it can be represented with Equation (6.1).

$$\varepsilon(k\Delta t) = D_0 \sigma(k\Delta t) + \sum_{i=0}^{k} D_1 \left(\Delta t(k-i) \right)^m (\Delta \sigma_i) \qquad (6.1)$$

where

$\Delta t = t_i - t_{i-1}$, the time interval,

$\Delta \sigma_i = \sigma_i - \sigma_{i-1}$, the change in stress and

k = the order of the time interval at which the strain is calculated.

Figures 6.2 and 6.3 illustrate computing of ε_r from $\varepsilon(t)$ for the pulse stress that represents the field loading and the laboratory M_R loading, respectively. Figure 6.2 shows that ε_r is the maximum value of the pulse strain history under field loading.
Figure 6.2: The resilient strain of the field pulse stress

133

An assumption is made that the rest duration between two consequent wheel loads is long enough to allow ε_r to be fully recovered. This assumption simplifies the frequency calculation since the rest duration depends on design traffic characteristics that are configuration of the axle load, traffic volume and traffic speed.

The recoverable strain of M_R whether it is the instantaneous (ε_i) or total (ε_t) strains is calculated for pulse with a total cycle period of one second consisting of loading time of t_p and a rest period of ($1-t_p$). ε_i is measured at the end of the unloading portion and ε_t is measured at the end of the rest period. Figure 6.3(a) shows process of computing of ε_i and ε_t following a procedure described by the test protocol of LTPP P07 for the determination of the instantaneous deformations from deformation-time plots. The LTPP P07 procedure is described for a sinusoidal pulse load of 0.1s followed by a rest period of 0.9s. To account for other loading times, this procedure has been re-defined in terms of t_p, as shown in Figure 6.3. Two regression lines are constituted from the strain history.

Figure 6.3(b) shows that regression line 1 is developed from the strain-time data of the unloading portion from $\dfrac{t_p}{6}$ to $\dfrac{t_p}{4}$ measured from the peak strain. Regression line 2 is developed from strain-time data of the last 0.2 s of the rest period. ε_i is measured between the peak strain and the strain at the intersecting point of the regression lines 1 and 2, and ε_t is the strain difference at the peak and the end of the rest period.
Figure 6.3. Definition of the resilient strain of M_R

(a) Constructing regression line 2. (b) Constructing regression line 1

f is the frequency of $|E^*|$, at which ε_0 resulting from subjecting AC to a normalized continuous sinusoidal stress is equivalent to ε_r. Knowing ε_r, f can be calculated as

follows. First, $|E^*|$ is calculated from ε_o and σ_o. Second, $|E^*|$ can be obtained as function of f for the given AC creep compliance parameters. Equations (2.23 and 2.24) are used to calculate the complex creep compliance (D^*) as a function of f. Then $|E^*|$ as a function of f can be obtained by applying Equations (2.11 and 2.30). Finally, f is determined by equating the $|E^*|$ value obtained from the first step and $|E^*|$ as a function of f.

6.2.1 Computing creep compliance parameters from the dynamic modulus

The creep compliance parameters, D_0, D_1 and m, can be determined from static creep, cyclic creep ($|D^*|$) and $|E^*|$ tests. Kim et al. (2005) concluded that the choice of the test method has a significant effect on the creep parameters. The effect results from the sensitivity of AC to loading rate. The cyclic tests can accurately characterize AC under short loading times while the static test can characterize it under long loading times. To determine a representative relationship between f and t_p, D_0, D_1 and m should be obtained from cyclic tests since the duration of the pavement pulse load is short with respect to the loading time of the static creep test, which at least is 100 seconds. These parameters have been determined for S1-S4 and B1-B4 at four temperatures from $|E^*|$ using Equations (2.27 to 2.34) by applying an approach described by Kim and Lee (1996) as follows:

1. Calculating $E`$ and $E``$ from measured $|E^*|$ and ϕ values at multiple frequencies using Equations (2.12 and 2.13).

2. Calculating $D`$ and $D``$ at $f$ using Equation (2.29). Table 6.1 lists $D`$ and $D``$ of S1.

3. Solving Equation (2.33) for D_0, D_1 and m using the least square technique.

Table 6.1(a): Storage complex creep compliance of S1

Temperature	Storage creep compliance (1/GPa)					
	25 Hz	10 Hz	5 Hz	1 Hz	0.5 Hz	0.1 Hz
-10	0.032	0.034	0.034	0.043	0.045	0.054
5	0.045	0.058	0.063	0.084	0.117	0.179
25	0.167	0.219	0.280	0.503	0.708	1.407
40	0.527	0.765	1.122	2.393	3.231	5.297

Table 6.1(b): Loss complex creep compliance of S1

Temperature	Loss creep compliance (1/GPa)					
	25 Hz	10 Hz	5 Hz	1 Hz	0.5 Hz	0.1 Hz
-10	0.004	0.005	0.006	0.009	0.011	0.015
5	0.009	0.016	0.019	0.033	0.053	0.093
25	0.083	0.122	0.161	0.312	0.486	0.902
40	0.322	0.442	0.651	1.359	1.823	2.444

Table 6.2 lists D_0, D_1 and m of S1-S4 and B1-B4. These values have been obtained by least square technique where initial values are assumed, and then the sum of the least square errors is minimized. D_0 at 40°C for most mixtures was a negative value so the solution was carried again forcing D_0 to be zero indicating fully viscous material. Table 6.2 has been used to validate the numerical integration shown by Equation (6.1) and to investigate the relationship between the loading time of the pulse stress and the loading frequency of the sinusoidal continuous stresses. Using the GPL model to represent the creep compliance of AC has some advantages. The GPL is a simple model since it has three parameters and each of them describes a material property where D_0 represents the response at very short loading time, D_1 represents the viscoelastic property at one second and m represents the viscous (creep) property. In addition, $|E^*|$ can be calculated exactly

for each set of parameters by applying Equations (2.27 to 2.34) without numerical integration. Furthermore, GPL parameters represent AC viscoelastic property at a specific temperature, so they can help in investigating the effects of temperature and AC stiffness on the relationship between the pulse loading time and frequency. Underwood and Kim (2009) used Prony series to represent the creep compliance of AC to determine $\varepsilon(t)$, and the number of the Prony series terms changed from a mixture to another.

Table 6.2: Calculated power model parameters of $D(t)$ from $|E^*|$ of laboratory mixtures

6.2.2 Validation of the Numerical Integration

The numerical convolution integral shown by Equation (6.1) has been validated through calculating $|E^*|$ and M_R of B2-B4. Figure 6.4 shows the comparison between the measured and calculated $|E^*|$. Figure 6.5 compares the calculated instantaneous and total resilient moduli with the measured values. The ε_0 of AC subjected to a normalized sinusoidal stress at various frequencies has been obtained from $\varepsilon(t)$ that is calculated numerically by using Equation 6.1 and then $|E^*|$ is calculated by applying Equation 2.11. Similarly, the instantaneous and total M_R values have been obtained by applying Equation 6.1 using a normalized sinusoidal pulse with loading time of 0.1s followed by a rest period of 0.9s.
Figure 6.4: Comparison between measured and calculated dynamic modulus
(a) Instantaneous resilient modulus
(b) Total resilient modulus

Figure 6.5: Comparison between the measured and calculated resilient modulus

The resilient strain including ε_i and ε_t has been obtained from $\varepsilon(t)$ using the procedure described with Figure 6.3. Then, the instantaneous and total M_R values are determined by applying Equation (2.54).

Figures 6.4 and 6.5 illustrate effectiveness of the proposed numerical convolution integral to calculate AC stiffness and consequently the strain from the parameters of the creep compliances. Since D_0, D_1 and m have been calculated from the measured $|E^*|$ values, high agreement is shown between the calculated and measured $|E^*|$ values are comparable. Figure 6.5 shows that the calculated M_R values from the axial loading are in good agreement with the measured M_R using the indirect tensile loading. This finding agrees with the literature where Kim et al. (2004) concluded that there is no significant difference between $|E^*|$ determined from both the axial loading and the indirect tensile loading within LVE range.

Performing the integration shown in Equation (6.1) numerically has many benefits. First, it facilitates applying the approach for asymmetric $\sigma(t)$ such as field-measured stresses even without knowing the pulse loading time. Symmetric $\sigma(t)$ can be represented with an equation such as haversine, bell-shape, sinusoidal and squared pulse shapes. While asymmetric $\sigma(t)$ could be measured from the field or obtained from a viscoelastic analysis. AC shows delayed response especially in the unloading portion. Second, numerical integration helps incorporating the rest period especially for laboratory-applied pulses to determine the resilient strain (ε_r). Finally, $\varepsilon(t)$ can be obtained without the need to perform complex integrations.

6.3 Time-Frequency Conversion Equations for Pulse Stresses

The proposed approach has been applied to determine the loading frequency (Hz) as a function of pulse loading time (s) for the following cases:

- Pulses used to represent the field pavement stress such as haversine (Equation 2.41), the bell-shape (Equation 2.42), sinusoidal ($0.5\left[1-\cos(\frac{2\pi}{t_p}t)\right]$) and square forms.

- Sinusoidal pulse used for laboratory M_R testing.

- The load history of the Falling Weight Deflectometer (FWD).

Table 6.3 lists the average of the frequencies (Hz) at selected pulse loading time (second) of the field pulse stress. The frequency has been calculated at each loading time for B1-B4 at -10, 5, 25 and 40°C. The percent coefficient of variation (CV) has been calculated at each loading time. Generally, CV is low and it increases with the shift of the pulse from the sinusoidal stress form of $|E^*|$. The CV is the highest for the squared pulse. In contrast, CV decreases with the loading time. The frequency of the bell-shape pulse is not presented in Table 6.3 since this pulse is controlled with the standard deviation (s) as shown in Equation (2.42).

Figure 6.6 shows the relationship between the frequency and the loading time for the sinusoidal pulse stresses. The relationship is well represented with a straight line on the log-log chart. There is strong relationship between the frequency and the loading time.

Table 6.3: Mean and coefficient of variation (CV) of the frequency at various loading times of pulse stresses

Loading time (s)	Sinusoidal pulse		Haversine pulse	
	Frequency (Hz)	CV (%)	Frequency (Hz)	CV (%)
1.00	0.37	2.3	0.30	7.5
0.50	0.74	2.6	0.58	8.2
0.40	0.92	2.7	0.73	8.5
0.30	1.23	2.8	0.97	8.8
0.20	1.83	3.2	1.44	9.3
0.10	3.65	3.5	2.83	10.0
0.05	7.25	3.9	5.58	10.6
0.02	18.02	4.3	13.69	11.3

Loading time (s)	Triangular pulse		Squared pulse	
	Frequency (Hz)	CV (%)	Frequency (Hz)	CV (%)
1.00	0.45	3.5	0.11	9.0
0.50	0.90	3.8	0.21	9.5
0.40	1.12	3.9	0.26	9.7
0.30	1.50	4.1	0.35	9.9
0.20	2.24	4.3	0.52	10.2
0.10	4.41	5.4	1.03	10.9
0.05	8.77	6.1	2.03	11.5
0.02	21.81	6.8	4.97	12.1
Figure 6.6: Loading time-frequency relationship for the sinusoidal pulse stress

The relationship can be represented with the following equation form.

$$f = \frac{k}{t_p} \qquad (6.3)$$

where

k = constant depends of the pulse shape form.

Table 6.4 lists the conversion equations and their coefficients of determination (R^2) for the pulse forms under investigation. For the bell-shape function, it has been assumed that t_p is four times of the standard deviation (s) that controls the curve. It is clear that each of

these equations has *k*-value less than one. This means that using Equation (2.35) overestimates the loading frequency whatever is the pulse stress form. Overestimating the frequency leads to a higher $|E^*|$ and consequently un-conservative pavement design where the pavement performance is expected to be underestimated. Al-Qadi et al. (2008b) found that the field stress can be represented with the normalized bell-shape. Equation (2.35) overestimates the frequency with 131% error, and Equation (2.36) underestimates the frequency with 63% error.

Table 6.4: Pulse time-frequency equivalences

Criteria	Sinusoidal pulse	Haversine pulse	Bell-shape pulse	Triangular pulse	Squared pulse
Equivalent frequency	$\dfrac{0.366}{t_p}$	$\dfrac{0.368}{t_p}$	$\dfrac{0.432}{t_p}$	$\dfrac{0.449}{t_p}$	$\dfrac{0.105}{t_p}$
Coefficient of determination (R^2)	0.997	0.981	0.997	0.994	0.979

The equivalent frequency for the sinusoidal pulse loading time of the M_R testing is determined by applying the approach including the procedure of computing ε_i and ε_t. Table 6.5 lists the equivalent frequency at selected pulse loading times where the frequency has been determined based on ε_i. Table 6.5 can be represented with the following equation.

$$f = \frac{0.496}{t_p} \tag{6.4}$$

From comparing Equation (6.4) with the conversion equation for the sinusoidal pulse shown in Table 6.4, the definition of the resilient strain has significant effect on the determined frequency. Figure 6.2 and Figure 6.3 show the determination of the resilient

strain from the strain-time history for calculating the equivalent frequency of field pulse loading and the equivalent frequency of the resilient modulus, respectively. Furthermore, Equation (6.4) indicates that both the approaches represented with Equation (2.35 and 2.36) are incorrect. Equation (2.35) overestimates the frequency by 50.4% while Equation (2.36) underestimates the frequency by 68%.

Table 6.5: Equivalent frequencies for loading pulse for instantaneous resilient modulus

Loading time (s)	Frequency (Hz)	CV (%)
0.03	13.30	0.93
0.05	8.32	0.48
0.10	4.70	0.77
0.20	3.04	1.71
0.30	2.32	1.75
0.40	1.92	1.25

The equivalent frequency of the FWD load history has been obtained by the proposed approach. Figure 6.7 shows the normalized FWD load and deformation histories. It can be seen that the deformation was collected over a short period compared to the M_R pulse load that allows a rest period with nine times of the pulse time. Consequently, the calculation of pavement stiffness including AC stiffness is based on the instantaneous response of FWD loading. Herein, the equivalent frequency of the normalized FWD pulse stress is calculated by applying the same procedure of determining the equivalent frequency of M_R pulse loading. It has been found that the equivalent frequency is 15.7 Hz with CV of 7%. If the deformation collected over a long time that is enough to catch the

delayed response of the pavement and the FWD backcalculated stiffness is determined based on the maximum resilient deformation, the equivalent frequency will be 13 Hz with CV of 5%.
Figure 6.7: Normalized load and deformations of FWD load drop

6.4 Impact the Loading Time-Testing Frequency Conversion

Figure 6.8 shows the $|E^*|$ master curve of B2 plotted as a function of the reduced time that is calculated based on the current MEPDG approach with Equation 2.35 and on the proposed approach considering field haversine pulse stress. Figure 6.8 shows that the MEPDG approach overestimates $|E^*|$ at all frequencies and the difference increases at low $|E^*|$ leading to overdesigned pavement structure. Rutting is sensitive to low stiffness and it may be underestimated in this manner.
Figure 6.8: Dynamic modulus master curve of B2 as a function of the loading time

6.5 Discussion of Frequency-Time Conversion

The f-t_p conversion is consistent with findings from literature. Kim and Lee (1996) found experimentally that the backcalculated FWD moduli are equivalent to measured $|E^*|$ of field cores values at 16 Hz, which is close to the calculated mean of 15.7 Hz with CV of 7%. In the same research, it was found that the measured M_R values is higher than $|E^*|$ at 5 Hz and generally lower than $|E^*|$ at 10 Hz. According the proposed approach, the equivalent frequency of M_R measured at 0.1s pulse time is 5 Hz.

The proposed conversion equations indicate that the MEPDG approach overestimates the frequency by up to 173% of the value calculated based on the viscoelastic theory. The

overestimation of the frequency depends on the pulse shape of the field stress.

Since the approach applies the viscoelastic theory and uses a numerical computation to determine the strain history, it can be applied to determine the frequency of field pulse stress without the need to determine the loading time. The field stress shows delayed response and residual stresses and consequently the symmetric pulse form may not fit it well (Al-Qadi et al., 2008b) so the actual stress should be used to obtain the exact equivalent frequency.

The Fast Fourier Transform (FFT) analysis has been carried out to determine the equivalent frequency of the FWD pulse load. The dominant frequency according to the approach proposed by AL-Qadi et al. (2008-b) is 15.83 Hz. This frequency is the same as the frequency calculated according to the proposed approach and considering the instantaneous strain. This strain neglects the delayed response of AC; so it is close to the elastic response. According to the proposed approach and considering the delayed response, the frequency was 13 Hz. Consequently, FFT approach in its current form may overestimate the frequency of the field pulse stresses.

6.6 Summary

An approach has been introduced to convert the pulse loading time to frequency at which the dynamic modulus can be used in multilayer elastic analysis. The conversion utilizes the viscoelastic theory to calculate the recoverable strains of AC subjected to the normalized sinusoidal continuous stress and the normalized pulse stresses. The frequency

is calculated at a given loading time when both the recoverable strains are equivalent. The numerical computation of the strain histories made easy incorporating different pulse shapes and the rest periods and AC has been modeled with the creep compliance that is represented with general power law. The creep compliance parameters have been obtained from the dynamic modulus and phase angle to represent accurately the short loading time of traffic. The approach differentiates between the field pulse stress and the laboratory applied pulse stress used for AC characterization since both of them are followed with different rest periods.

The numerical integration shows the ability to calculate with significant accuracy both the measured dynamic and resilient moduli. The approach can calculate the frequency for any pulse shape whether it is collected from the field or from the pavement analysis. It can be applied to determine the frequency for special AC mixtures such as Stone Matrix Asphalt (SMA) if the creep compliance of a mixture is represented by the Equation (2.4).

Conversion equations have been developed based on the proposed approach to convert the loading time of the common pulse shape forms in pavement analysis to the frequency. It has been showed that the current approach of MEPDG overestimates the frequency with up to 171% depending on the pulse form. Furthermore, FFT method to determine the frequency content of the pulse and the dominant frequency has been shown to overestimate the frequency slightly.

The approach has been applied to determine the equivalent frequency for M_R and FWD

backcalculated stiffness. Both M_R and FWD stiffness are used in pavement evaluation and rehabilitation along with the dynamic modulus. Finding the equivalent frequency increases the reliability of pavement evaluation and design.

7 Predicting the Dynamic Modulus from Resilient Modulus Tests

7.1 Approach of Predicting |E*| from MR

Figure 7.1 illustrates the proposed approach to predict $|E^*|$ from M_R. The approach uses three relationships: the pulse loading time (t_p) and its equivalent frequency (f_{eq}), $|E^*|$ and temperature at a given frequency, and the shift factor and temperature. Equation 6.4 is used to determine f_{eq} for a given t_p of sinusoidal pulse load. For a pulse form other than the sinusoid, the approach presented in chapter 6 can be followed to calculate the equivalent frequency. At f_{eq}, $|E^*|$ is equivalent to the measured M_R at 5, 25, 40°C.

$|E^*|$ at any temperature can be interpolated from the equivalent $|E^*|$ at three temperatures using a function that represents reasonably the $|E^*|$ isochronal curve, Figure 2.5(b), at f_{eq}. The isochronal curve function can be used to predict $|E^*|$ at any temperature. Three functions have been examined to represent the isochronal curve and interpolate $|E^*|$. Applying the time-temperature superposition, $|E^*|$ at f_{eq} as a function of temperature can be generated from master curves. The process of selecting an interpolation function for $|E^*|$ at f_{eq} of 5 Hz is introduced and it can be followed to determine another interpolation function for $|E^*|$ at different frequencies. For f_{eq} of 5 Hz, the quadratic function represents reasonably well the $|E^*|$-temperature relationship using $|E^*|$ at 5 Hz and 5, 25 and 40°C. Furthermore, the quadratic function is assessed to interpolate $|E^*|$ from the three

equivalent values.

The required third relationship is the shift factor with temperature. One of shift techniques presented in section 2.4 can be used to determine this relationship.

7.2 Predicting $|E^*|$ from M_R

7.2.1 Equivalent Frequency

For M_R pulse load of 0.1 s, f_{eq} is 5 Hz that is calculated using Equation 6.4. The B2-B4 and G5 mixtures are used to show that f_{eq} is practically the most reasonable value among the test frequencies. G5 consists of four mixtures, S12.5C, S12.5FE, S12.5CM and B25.0C. The G5 mixtures are used in North Carolina and documented in (Lacroix 2008). Aggregates of G5 were classified as coarse material with various gradations. Dataset of these mixtures consisted of $|E^*|$ and M_R values obtained in IDT test mode. Figure 7.2 shows the boxplot of the ratio of $|E^*|$ to M_R calculated at five frequencies (0.1, 1, 5, 10 and 25 Hz).
Figure 7.2: The ratio of $|E^*|$ to M_R at the loading frequency, B2-B4 and G5 mixtures

For each boxplot, the centre horizontal line represents the median value of the ratio, and the upper and lower horizontal lines that outline the box represent the 90th and 10th percentiles, respectively. The vertical lines extending above and below the box indicate the spread of the ratio.

The values of the ratio at each frequency are obtained from seven mixtures and three temperatures each. The ratio increases with frequency as expected as $|E^*|$ increases. The figure confirms the calculated f_{eq} of 5 Hz where the ratio has a median value of 0.99 with a spread of the ratio increasing with moving far away from 5 Hz. The frequency calculated based on the MEPDG approach shown by Equation (2.35) is 10 Hz. On the other hand, the frequency calculated based on the angular frequency approach shown by Equation (2.36) is 1.67 Hz. Figure 4.10 indicates that the first approach overestimates the ratio of $|E^*|$ to M_R with 15% and that the second approach underestimates the ratio with 35%. Furthermore, Figure 7.3 shows a strong relationship ($R^2 > 0.99$) between M_R and $|E^*|$ at 5 Hz.

Lacroix et al. (2007) determined M_R from $|E^*|$ using the elastic-viscoelastic corresponding principle. For G5, the difference of both the calculated M_R using Lacroix et al. (2007) and $|E^*|$ at 5 Hz from the measured M_R is presented in Figure 7.4. It is noticed that $|E^*|$ at 5 Hz is almost as good as M_R. From Figures 7.2 to 7.4, Equation 6.4 gives f_{eq} comparable with the laboratory measurements and analytical approach of Lacroix et al. (2007).

et al. (2007) approach

156

7.2.2 Interpolation Function of $|E^*|$

M_R of the laboratory and field compacted AC specimens shown in Table 3.1 has been used to select the function that reasonably represents the M_R-temperature relationship. The power, exponential and quadratic functions, Equations 7.1-7.3 respectively, represented the relationship between M_R and temperature with $R^2>0.98$. The accuracy of these functions is examined to interpolate $|E^*|$.

$$\left|E^*\right|(T) = c_1(T + c_2)^{c_3} \tag{7.1}$$

$$\left|E^*\right|(T) = c_4 e^{c_5 T} \tag{7.2}$$

$$\left|E^*\right|(T) = c_6 T^2 + c_7 T + c_8 \tag{7.3}$$

where,

T = temperature (°C)

$c_1 - c_8$ = regression constants

The accuracy of the interpolation is represented by the percent difference and the percent Root Mean Square Error (%RMSE), which are obtained as follows:

$$\text{Percent difference } (T) = \frac{\text{interpolated } |E^*| \, (T) - \text{measured} |E^*|(T)}{\text{measured} |E^*|(T)} \times 100 \tag{7.4}$$

$$\%RMSE = \sqrt{\frac{\sum\limits_{j}^{M}\sum\limits_{i}^{N}\left(\text{Percent difference } (T_i)\right)_j^{2}}{NM}} \tag{7.5}$$

where N is number of temperatures and M is the number of mixtures.

$|E^*|$ of S1-S4 and B1-B4 has been used to evaluate the ability of Equations 7.1 to 7.3 to interpolate $|E^*|$ at any temperature. On one hand, the parameters of master curves and shift factors listed in Table 4.1 are used to generate $|E^*|$ at a set of temperatures (-10 to

40°C with a 5°C step). The shift factor at any temperature is interpolated from those shift factors using a quadratic function. On the other hand, $|E^*|$ at the set of temperatures has been interpolated from M_R at three temperatures using each one of Equation 7.1 to 7.3. Figure 7.5 shows the prediction error and %RMSE.
Figure 7.5: The accuracy of the functions proposed to interpolate $|E^*|$ of S1-S4 and B1-B4 from three equivalent $|E^*|$.

The quadratic function predicts $|E^*|$ with a percent difference up to 25%. The range of the percent difference is ± 10 % of the measured values at the intermediate stiffness (2000 – 10000 MPa) and ± 25 % at higher and lower stiffness. Furthermore, the %RMSE for the quadratic function is 11 % while it is 21 % and 53 % for the exponential and power law functions respectively. The power function overpredicts $|E^*|$ at high stiffness with up to 275% of the measured values. The exponential function underestimates mostly $|E^*|$ at high stiffness with -50 % and higher while overpredicts $|E^*|$ at low stiffness with up to 50%. Accordingly, the quadratic function is the best choice among the examined functions to interpolate the $|E^*|$ at f_{eq} at any temperature from M_R.

7.3 Predicted |E*| Master Curve

Figure 7.6 shows the predicted and the measured $|E^*|$ master curves of B2-B4 mixtures. The predicted master curves were developed from M_R at 5, 25 and 40°C according to the proposed approach shown in Figure 7.1 as follows:

1. Given the pulse duration of M_R of 0.1s, f_{eq} can be calculated using Equation 6.4. Consequently $|E^*|$ at 5 Hz is equivalent to M_R.

2. The quadratic function shown in Equation 7.3 is used to interpolate the equivalent $|E^*|$ from M_R at temperatures (-10 to 40°C with 5°C).

3. Developing the shift factor-temperature relationship. Lacroix et al. 2008 found that the shift factor of binder can be used to construct the $|E^*|$ master curve. Herein, the shift factors listed in Table 4.1 of B2-B4 mixtures are applied.

4. Constructing the $|E^*|$ master curve by shifting the interpolated $|E^*|$. Coefficients of the sigmoidal function can be determined from the shifted values using the non-linear

fitting technique. Figure 7.6 shows that the proposed approach can predict $|E^*|$ master curves of B2-B4 from M_R. Figure 7.7 compares the predicted and the measured $|E^*|$ of B2-B4 and G5 mixtures. The predicted master curves are as accurate as those developed from measured values and can efficiently differentiate between B2-B4 based on their load response. The approach predicts $|E^*|$ at middle and low frequencies where AC is sensitive to rutting and fatigue cracking.
Figure 7.6: Comparison of the predicted and the measured $|E^*|$ master curves
Figure 7.7: The accuracy of the proposed approach to predict $|E^*|$ from M_R of B2-B4

mixtures and G5 mixtures

7.4 Summary

An approach has been introduced to predict $|E^*|$ from M_R using three relationships, pulse loading time and frequency, $|E^*|$ and temperature, and the shift factor and temperatures. In this chapter, the relationship between $|E^*|$ and temperature has been investigated and the quadratic function that has three constants has been introduced and investigated to represent this relationship.

The approach has been used to predict $|E^*|$ of seven mixtures from M_R that is measured at

three temperatures. The predicted and measured $|E^*|$ have good agreement. The predicted $|E^*|$ master curve has the ability to differentiate between mixtures similarly as the measured $|E^*|$ master curve. The approach can be used to predict $|E^*|$ of field cores from M_R since it does not depend on properties AC mixtures such as the Witczak $|E^*|$ prediction model. $|E^*|$ of field cores can be used to evaluate in-service pavement and in construction quality control.

8 Conclusions, Limitations and Recommendations

8.1 Summary and Conclusions

One of the major advancements in the mechanistic-empirical pavement design is using $|E^*|$ that, in contrast of other stiffness parameters, is a fundamental stiffness describing the actual viscoelastic behaviour of asphalt concrete. Through $|E^*|$, factors that affect behaviour of asphalt pavement such as traffic speed, temperature and aging are incorporated in pavement design. In addition, $|E^*|$ is an SPT parameter that can compare asphalt mixtures against the pavement performance. Therefore, an accurate determination of $|E^*|$ is essential for improving the reliability of pavement design and for evaluating the asphalt mixtures. The thesis contributes research on improving the reliability of prediction of $|E^*|$ at high temperature, improving the determination of the quasi-elastic modulus of asphalt concrete for pavement design, and predicting $|E^*|$ from M_R of asphalt concrete to determine in-service stiffness.

Current methods for predicting $|E^*|$ are less reliable at high temperatures which increases uncertainty in the forecasted pavement performance and the estimated service life. Aggregate gradation has a dominant effect particularly at high temperature where the binder stiffness is low. A gradation ratio, GR, that is the ratio of passing 4.75 mm sieve to 0.075 mm sieve has been used to describe the relationship between aggregate gradation and $|E^*|$ at 40⁰C, $\left|E_{40}^*\right|$.

The $\left|E_{40}^*\right|$-GR model has been developed by the linear regression analysis to adjust the

163

predicted $|E^*|$ master curves. Data of twenty-four mixtures prepared from various aggregate types and gradation, and various binder grade has been used to investigate the relationship and to develop the model.

Furthermore, to determine the appropriate $|E^*|$ for the multilayered elastic analysis of asphalt pavement system, the frequency of the applied load is calculated as a function of the loading time that depends on the traffic speed and the pavement thickness and stiffness. Therefore, the reliability of load representation in pavement design depends on correctness of the loading frequency. The pulse time-frequency conversion approach, based on viscoelastic theory, has been introduced to determine the equivalent frequency for a given loading pulse. The approach calculates a quasi-elastic modulus of asphalt concrete under a pulse load. Similar to $|E^*|$, the quasi-elastic modulus is the ratio of the maximum stress to the maximum strain under the pulse load. Then, the frequency of the applied load is calculated from the $|E^*|$-frequency relationship when the quasi-elastic modulus is equivalent to $|E^*|$. Asphalt concrete has been characterized with the creep compliance represented by parameters of the general power law, D_0, D_1 and m, to determine numerically the quasi-elastic modulus and to define the $|E^*|$-frequency relationship. Conversion equations have been developed to calculate frequency from pulse time of field loading and laboratory pulses.

Finally, the method of predicting $|E^*|$ from M_R has been introduced to develop the entire $|E^*|$ master curve from M_R. The equivalent frequency, f_{eq}, at which $|E^*|$ is equivalent to M_R is calculated by applying the pulse time-frequency conversion approach. Then, the parabolic function is used to interpolate $|E^*|$ at f_{eq} and a wide range of temperature from M_R at three

164

temperatures. The interpolation is carried out to generate sufficient $|E^*|$ values to substitute the measured $|E^*|$ at various frequencies and temperatures. Finally, the interpolated values at f_{eq} are shifted with the shift factor of the binder. The method has been verified with measured $|E^*|$ and M_R from mixtures tested during the experimental program and other mixtures from literature.

Conclusions are drawn:

1. Improving the prediction of $|E^*|$ at high temperature

- The relationship between $\left|E^*_{40}\right|$ and aggregate gradation represented by GR should be studied independently in fine-graded and coarse-graded mixtures.

- For fine-graded mixtures, the relationship is statistically significant regardless of the binder grade.

- The $\left|E^*_{40}\right|$-GR model has been developed to adjust the predicted $|E^*|$ at high temperature for fine-graded mixtures. The model, Equation 5.2, is calibrated with data from 11 fine-graded mixtures and has goodness of fit of $R^2 = 0.89$ and $S_e/S_y = 0.35$.

- $|E^*|$ master curves predicted using the Witczak model have been adjusted using $\left|E^*_{40}\right|$ calculated from GR of mixtures. The adjustment improves the prediction of $|E^*|$ especially at high temperatures.

- The relationship between stiffness at high temperature and GR is examined in as-constructed AC mixtures using M_R at 40°C. The relationship is significant even within mixtures containing RAP.

- The relationship between $|E^*|$ at high temperature and GR can be used as a guide to optimize aggregate gradation of fine-graded mixtures for higher $|E^*|$. It can also be used for construction quality control by defining M_R that should be reached as a function of gradation.

2. Pulse Time-Test frequency conversion

- The factors affecting pulse time-frequency conversion have been investigated. It was found that the equivalent loading frequency depends significantly on the pulse load form and to a lesser extent on the viscoelastic property of asphalt concrete and temperature. Conversion equations, Table 6.4, were developed for the following field loading forms: haversine, bell-shape form, triangular and square.

- The MEPDG approach overestimates the loading frequency by up to 173% depending on the shape of the field stress. On the other hand, the approach that applies the angular frequency underestimates it by up to 65%. Since $|E^*|$ increases with the frequency, MEPDG overestimates the design value of $|E^*|$.

- The equivalent frequency of the M_R pulse load, for instantaneous resilient modulus, is the one-half inverse of pulse time. For example, the frequency of a 0.1s pulse load is 5 Hz. In addition, the equivalent frequency of FWD loading history is 15.7 Hz. Both M_R and backcalculated FWD stiffness are used in pavement evaluation and rehabilitation. The determination of their equivalent frequencies increases the reliability of pavement evaluation and design.

- Since the conversion approach applies a numerical integration scheme, the loading frequency of any pulse stress can be calculated even for asymmetric pulses. In addition,

the approach can be applied to determine the loading frequency when special mixtures such as Stone Matrix Asphalt (SMA) or mixtures that containing modified binders are used. The creep compliance of a mixture must be represented accurately by the power function to apply the approach.

3. Predicting $|E^*|$ from M_R

- The method of predicting $|E^*|$ from M_R has been successfully verified for the laboratory compacted mixtures. The parabolic function has interpolated $|E^*|$ at various temperatures and 5 Hz, which is f_{eq} of 0.1 pulse load, from M_R at 5, 25, 40°C. The function was verified by using $|E^*|$ at f_{eq} generated from $|E^*|$ master curves. The predicted $|E^*|$ master curves match significantly the master curves developed from measured $|E^*|$. The method does not carry any constant value from materials, so it can be applied to predict $|E^*|$ of in-service asphalt concrete.

- The $|E^*|$ master curve can be predicted from a cheaper and faster test like the M_R test. The approach can be applied to predict $|E^*|$ from M_R measured under any pulse load after determination f_{eq} by applying the pulse time-frequency conversion approach. The method is useful for testing as-built and in-service pavements. In addition, the method can support using the M_R test for quality control (QC). Furthermore, the method can be beneficial for adapting the existing asphalt pavement databases, such as the LTPP database, to MEPDG.

8.2 Limitations and Recommendations

- The $|E^*_{40}|$-GR mode has been developed for fine-graded mixtures. For coarse-graded

mixtures, the relationship needs further investigation.

- The conversion equations of the pulse loading time to the frequency are obtained for AC tested in this thesis. Further investigation is required when they are used with AC mixtures containing modified binders or with special mixtures such as SMA.

- The conversion equations are developed for symmetric loading forms. The stress pulses from field pressure cells and those pulses from the viscoelastic analysis are asymmetric since the unloading portion of the pulse may contain residual stresses. The maximum pulse strain is mostly developed during the loading portion; therefore, the conversion equations may not be sensitive to the unloading portion. Further examination is required to evaluate the effect of the asymmetry of the loading and unloading portions.

- The conversion equations have been developed for forms used to represent vertical pulse stresses. The effect of adopting these equations in pavement design on the resulting tensile strain at bottom of the asphalt layer and the vertical stress on the base course should be examined by comparing results of viscoelastic and elastic analysis. The reliability of the fatigue cracking and rutting of the pavement foundation depends on the accuracy of the calculated tensile strain of asphalt concrete and the vertical stresses on the base course. Adopting the approach in pavement design requires recalibrating the pavement performance models.

- Equation (6.4) has been developed for instantaneous M_R obtained under sinusoidal pulse stress. For other pulse forms or for the total M_R, the equivalent frequency can be determined by applying the pulse time-frequency approach.

- The frequency of square loading pulse equals $\dfrac{0.105}{t_p}$ and it can be useful for determining

$|E^*|$ from an easy and fast test like the $D(t)$ test that can be carried out on laboratory and field specimens.

- The proposed approach to predict $|E^*|$ from M_R requires determination of the shift factor of the binder. For unaged binder, methods are available to calculate the shift factor from the binder rheology while, for in-service AC, the shift factor from field-extracted binders needs further investigation.

- Adapting the measured $|E^*|$ values is recommended for comparing between mixtures when small differences are expected between mixtures. M_R specimens can be damaged more easily due to cracking at the contact area between loading strips and the specimen affecting the accuracy of the predicted $|E^*|$ from M_R. In addition, the variability of $|E^*|$ test is generally smaller than the variability of M_R test.

Appendix B: Calibration of Testing Setup

This appendix presents calibration of the LVDTs and the extensometers, which are used in the testing program of the thesis. In addition, the dynamic modulus and the phase angle obtained by the two deformation measuring systems are compared. Both LVDT and extensometer measuring systems are discussed in 3.6. Since these systems are used to determine response of asphalt concrete, both collected displacement and the lag between the load and displacement have been calibrated.

Calibration of deformation measuring systems

Connected to the data acquisition, DAQ, each deformation measuring system is calibrated for displacement and phase angle. LabView is used to correlate between displacement and voltage measurements of each transducer. For calibrating LVDTs for displacement, a micrometer with precession of 2×10^{-6} m was used to measure the displacement. On the other hand, shunt calibration modules are used to calibrate the extensometers. The systems are used after calibration to measure displacements defined with the micrometer. Figure B.1 shows comparison of measured displacements and readings of the LVDTs for them.
Figure B.1: the relationship between displacement determined with LVDTs and those

measured with the micrometer
Figure B.2: Phase angle error between the applied load and displacement

184

A cylindrical aluminium specimen with thickness of 1 mm, 50.8 mm diameter, and 150 mm height has been used to determine the phase angle, if there, between the applied sinusoidal load and the collected sinusoidal displacement using LVDTs and extensometers. Figure B.2 shows the measured phase angle at various frequencies. Since Aluminium has elastic response, this phase angle represents the lag between the collected data of load and displacements. The measured phase angle with each of transducer suggests a linear relationship with frequency; therefore, the time lag between the load and displacements is constant and does not depend on the applied load. Phase angle of asphalt concrete is corrected from the time lag by taking off the measured phase angle shown in Figure B.2.

Comparison of LVDTs and Extensometers' measurements

Dynamic modulus test was carried out on B1 mixture and displacement of test specimens was collected simultaneously by both LVDTs and Extensometers. Figure B.3 shows the comparison between the measured dynamic modulus and phase angle with LVDTs and extensometers. There is no difference between dynamic modulus of B1 measured with LVDTs and that is measured with extensometers and for phase angle, there is small bias. Phase angle measured with LVDTs is slightly higher than phase angle measured with extensometers with about 1 degree.
