**Abstract.** The distributions of carbonate system parameters in Hudson Bay, which not only receives nearly one-third of Canada’s river discharge but is also subject to annual cycles of sea-ice formation and melt, indicate that the timing and magnitude of freshwater inputs play an important role in carbon biogeochemistry and acidification in this unique Arctic ecosystem. This study uses basin-wide measurements of dissolved inorganic carbon (DIC) and total alkalinity (TA), as well as stable isotope tracers ( $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}_{\text{DIC}}$ ), to provide a detailed assessment of carbon cycling processes within the bay. Surface distributions of carbonate parameters reveal the particular importance of freshwater inputs in the southern portion of the bay. Based on TA, we surmise that the deep waters in the Hudson Bay are largely of Pacific origin. Riverine TA end-members vary significantly both regionally and with small changes in near-surface depths, highlighting the importance of careful surface water sampling in highly stratified waters. In an along-shore transect, large increases in subsurface DIC are accompanied by equivalent decreases in  $\delta^{13}\text{C}_{\text{DIC}}$  with no discernable change in TA, indicating a respiratory DIC production on the order of  $100\ \mu\text{mol kg}^{-1}$  DIC during deep water circulation around the bay.

## 1 Introduction

The Arctic Ocean is particularly vulnerable to “ocean acidification” (defined as the combined results of decreasing pH and increasing calcium carbonate solubility), because changes in pH and carbonate ion concentration in response to a given uptake of atmospheric  $\text{CO}_2$  are more pronounced in cold, low-alkalinity waters compared to warm waters with high alkalinity. Furthermore, inflowing Pacific water with naturally high  $\text{CO}_2$  concentrations, as well as dilution from sea-ice melt and river waters, exacerbates the so-called “vulnerability” of polar waters (AMAP, 2013; Shadwick et al., 2013). Freshwater input can directly reduce the buffering capacity of seawater, and dilutes carbonate ions, thereby decreasing the saturation states of calcite ( $\Omega_{\text{Ca}}$ ) and aragonite ( $\Omega_{\text{Ar}}$ ), minerals that many important marine species require to form their shells (e.g., Chierici and Fransson, 2009; Yamamoto-Kawai et al., 2009). Therefore, regions of the Arctic Ocean are predicted to be among the first to experience the damaging effects of ocean acidification (Orr et al., 2005; Fabry et al., 2009).

The Hudson Bay system receives nearly one-third of Canada’s river discharge, and Hudson Bay itself goes from complete ice cover in winter to open water in summer, culminating in an annual freshwater yield from river runoff and sea-ice melt that is more than double that of the Arctic Ocean (Granskog et al., 2011). Organic matter respiration releases

**Figure 1.** Bathymetric map of the Hudson Bay system showing stations sampled during the 2010 ArcticNet mission (black dots). Shaded areas denote ice-covered regions as of 12 July 2010, determined using weekly regional ice extent maps (Environment Canada, Canadian Ice Service, <http://www.ec.gc.ca/glaces-ice/>). The location of the 185 m sill in the central channel connecting Hudson Bay with Foxe Strait and Hudson Strait is marked with a black star. The dashed box around the Nelson and Hayes River estuaries includes the stations shown in Fig. 5.

dissolved inorganic carbon (DIC) and consumes total alkalinity (TA), which decreases the  $\Omega_{Ca}$  and  $\Omega_{Ar}$  in deep waters. In addition to the organic matter generated in the euphotic zone by primary producers, local riverine inputs of organic matter are injected into deep waters during sea-ice formation (Mundy et al., 2010; Granskog et al., 2011). Furthermore, at the mouth of Hudson Bay, shallow sills restrict the exchange of deep water between the bay and the relatively well ventilated waters from the adjacent Hudson Strait or Foxe Strait (Granskog et al., 2011). Given these characteristics, Hudson Bay may be particularly vulnerable to ocean acidification. In support of this, Azetsu-Scott et al. (2014) recently provided the first basin-wide overview of the Hudson Bay carbonate system in fall 2005, reporting that surface waters in southeastern Hudson Bay, where freshwater inputs are highest, were undersaturated with respect to aragonite ( $\Omega_{Ar} < 1$ ), as were up to two-thirds of Hudson Bay bottom waters.

With air temperatures rising, sea-ice coverage declining, and increasing river diversion for hydroelectricity generation, conditions in the Arctic, and Hudson Bay in particular, are changing much more rapidly than in much of the world's oceans. The Hudson Bay system is one of the richest eco-regions for marine mammals in the world and is critical for both resident and migratory species (Wilkinson et al., 2009). Regime shifts in this ecosystem could therefore result in cascading effects impacting multiple organisms and coastal communities. The 2005 fall survey by Azetsu-Scott et al. (2014) provided an initial baseline for understanding of

the state of the  $CO_2$  system in Hudson Bay, yet significant uncertainties remain regarding the biogeochemical processes responsible for the observed state of the marine carbonate system and how the system and its controlling processes have changed, or may continue to change, over time.

Here, we present recent (July 2010) seawater measurements of the marine carbonate system along with stable isotope ratios of oxygen in seawater ( $\delta^{18}O$ ) and DIC ( $\delta^{13}C_{DIC}$ ) across Hudson Bay. Surface distributions highlight the impact of different freshwater inputs on the carbonate system. Relationships of DIC and TA with salinity in deep water provide insight into the origin of waters in Hudson Bay, while similar relationships in shallow water describe key sources and sinks of carbon. We also evaluate the evolution of water mass properties during transit around Hudson Bay and the importance of precise sampling techniques when working in highly stratified waters.

## 2 The Hudson Bay system

The Hudson Bay system, which includes James Bay to the south, and both Foxe and Hudson straits to the north, is shown in Fig. 1. Hudson Bay itself is the largest inland sea in North America (Martini, 1986), covering an area of 841 000 km<sup>2</sup> (Kuzyk et al., 2009). Hudson Bay is relatively shallow, with an average depth of 125 m and a maximum depth of 250 m, while areas of Foxe Strait and Hudson Strait reach depths of 400 m (Prinsenberg, 1987; Saucier et al.,

2004). Water enters the Hudson Bay system from two channels. Waters that are predominantly of Pacific origin enter from the north, flowing from the Canadian Archipelago into Foxe Basin and Foxe Strait via the Fury and Hecla Strait, while Atlantic waters enter from the east, flowing from the Labrador Sea into the Hudson Strait (Ingram and Prinsenberg, 1998). Hudson Bay is connected to Foxe and Hudson straits via four main channels. The narrow channel west of Southampton Island is only 50 m deep but is considered an important source of water to the northwest corner of the bay (Prinsenberg, 1986). The majority of water exchange occurs via three channels located between southwest Southampton Island and the east coast of Hudson Bay. The outer channels are only 130 m deep; thus, exchange of deep waters is likely limited to the central channel, which contains a sill at 185 m depth (Fig. 1, black star).

Within Hudson Bay, the circulation is generally cyclonic (counterclockwise), with a mean summertime current velocity of  $0.05 \text{ m s}^{-1}$  (Martini, 1986; Prinsenberg, 1986). During transit, coastal surface waters are substantially modified by river inputs, which total approximately  $760 \text{ km}^3 \text{ yr}^{-1}$  (Déry et al., 2011). The vast majority of this input enters via James Bay (47 % of the total) and from rivers along the southern coast (from the Churchill to the Great Whale; see Fig. 1) that drain directly into Hudson Bay (32 % of the total input). The peak river input ( $\sim 2 \text{ km}^3 \text{ day}^{-1}$ ) occurs in May, while the minimum ( $\sim 1 \text{ km}^3 \text{ day}^{-1}$ ) occurs in March (Déry et al., 2011). Freshwater is also added to surface waters via sea-ice melt (SIM). Hudson Bay is completely ice-covered for 8–9 months of the year and becomes completely ice-free in the summer. Sea ice can reach a maximum thickness of about 1 m in James Bay, 1.5 m in Hudson Bay, and 2 m in Foxe Basin (Martini, 1986). In Hudson Bay, peak inputs from SIM are from June to mid-July, and during this time SIM usually provides more freshwater to surface waters than river runoff (Prinsenberg, 1988; Granskog et al., 2011). The pulse of meltwater also creates strong vertical stratification, which suppresses mixing of heat and nutrients into the surface waters (Prinsenberg, 1988; Else et al., 2008). Ice formation is also responsible for brine formation due to salt rejection (Saucier et al., 2004; Granskog et al., 2011).

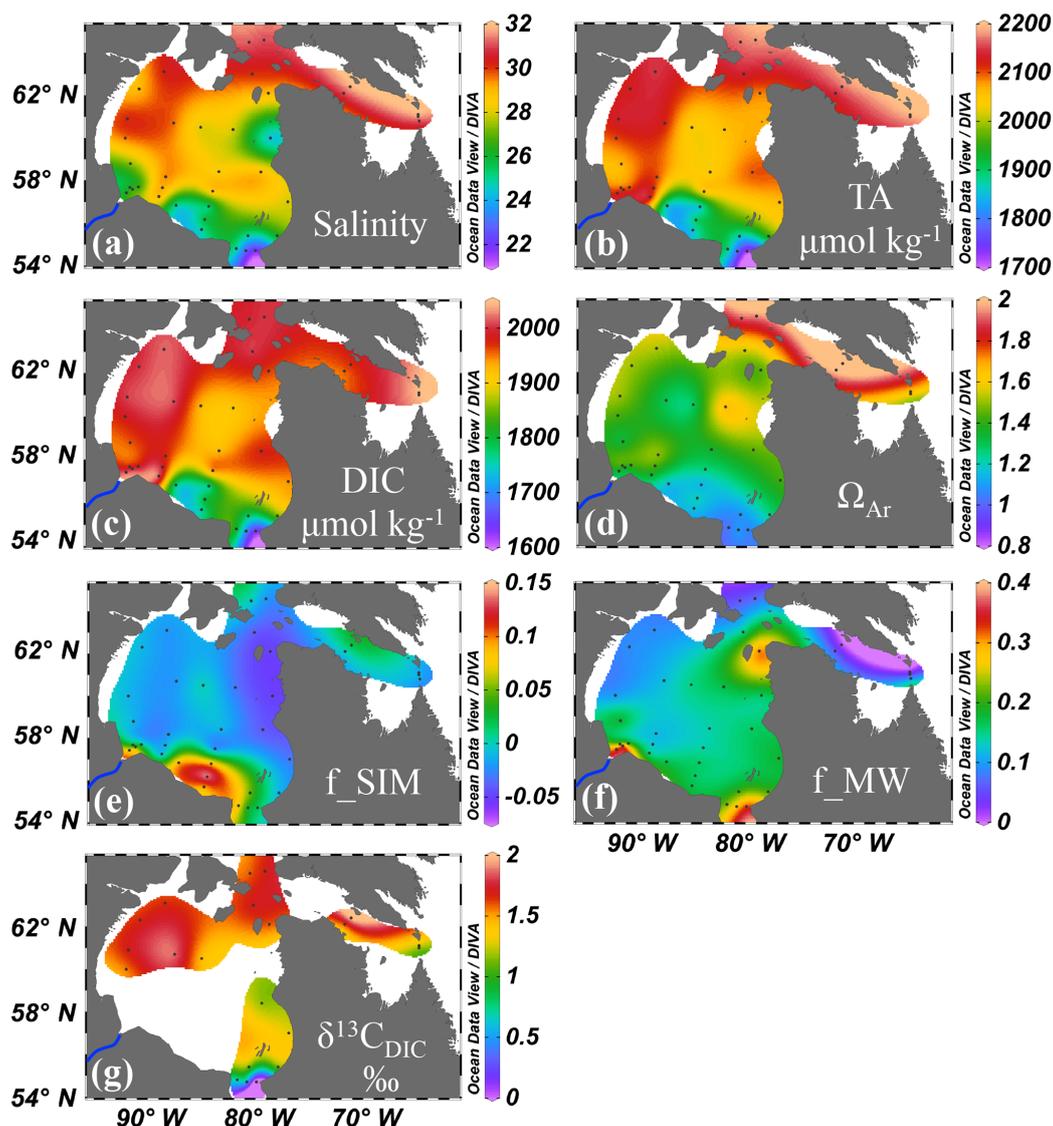

### 3 Methods

We collected samples at 55 stations, including 16 rivers, across the Hudson Bay system from 7 to 30 July 2010, during leg 1a of the 2010 ArcticNet cruise aboard the CCGS *Amundsen* (Fig. 1). Water samples for salinity, DIC, TA, and stable isotopes of both oxygen in seawater ( $\delta^{18}\text{O}$ ) and DIC ( $\delta^{13}\text{C}_{\text{DIC}}$ ) were collected at various depths using 12 L Niskin bottles mounted on a 24-bottle rosette fit with a Sea-Bird SBE911 conductivity–temperature–depth (CTD) profiler. Niskin bottles were held at each depth for 1 min before closing to allow for adequate flushing. A small subset

of samples collected in the Nelson River estuary, as well as river samples, were taken using either a single 3 L Niskin bottle hand-lowered to 1 m depth (for DIC, TA, and associated salinities) or a bucket hand-lowered to less than 1 m depth (for  $\delta^{18}\text{O}$ ,  $\delta^{13}\text{C}_{\text{DIC}}$ , and associated salinities).

Samples for DIC and TA determination were taken directly from the Niskin bottles into borosilicate glass bottles: 250 or 500 mL bottles with ground-glass stoppers and elastic closures or 250 mL screw-cap bottles. All DIC and TA samples were poisoned with  $100 \mu\text{L}$  of a saturated  $\text{HgCl}_2$  solution to halt biological activity and were stored in the dark at either room temperature or  $4^\circ\text{C}$  until being processed ashore. The DIC and TA determinations were conducted at both Dalhousie University in Halifax, Nova Scotia, and the Institute of Ocean Sciences (IOS) in Sidney, British Columbia. Both labs analyzed samples for DIC coulometrically followed by TA determination from the same bottle using potentiometric titrations. At Dalhousie, both DIC and TA were measured using a VINDTA 3C (Versatile Instrument for the Determination of Titration Alkalinity, Marianda), whereas IOS measured DIC using a SOMMA (Single-Operator Multiparameter Metabolic Analyzer) and TA with a custom-built titration system. The analytical methods followed the recommendations of Dickson et al. (2007). Both labs used certified reference materials (CRM batches 101 and 81) supplied by A. G. Dickson (Scripps Institution of Oceanography) to consistently calibrate the instruments. Samples measured by the IOS lab have an analytical precision better than 0.9 for DIC and  $2 \mu\text{mol kg}^{-1}$  for TA. An equivalent precision computation could not be done for samples analyzed at Dalhousie due to a lack of duplicate samples, but, historically, precision of the Dalhousie VINDTA system has been consistently better than  $3 \mu\text{mol kg}^{-1}$  (e.g., Shadwick et al., 2011). We computed the aragonite saturation state ( $\Omega_{\text{Ar}}$ ) from the DIC and TA data using the CO2SYS program of Lewis and Wallace (1998), with the equilibrium constants of Mehrbach et al. (1973) refit by Dickson and Millero (1987).

At station 740 in central Hudson Bay (Fig. 1), an intercalibration between the IOS and Dalhousie labs was conducted wherein duplicate samples were taken from all 12 Niskin bottles, with each lab producing independent depth profiles of both DIC and TA. Anomalously high deviations in both DIC and TA were measured at the bottom-most sample, and CTD profiles at this station reveal distinct changes in temperature and salinity in the bottom 4 m of the water column, suggesting the presence of a bottom nepheloid layer. Given that the bottom Niskin bottle was closed within this layer, the large deviations in both DIC and TA between duplicate samples may be due to large geochemical gradients or high concentrations of suspended material in the Niskin bottle. Not including these bottom samples, mean absolute differences in DIC and TA samples between the two labs were  $2.4 \pm 0.9$  and  $12.6 \pm 6.8 \mu\text{mol kg}^{-1}$ , respectively. Deviations in TA between the 11 duplicate samples (bottom sample not included) were not consistently positive or negative; thus, an

**Figure 2.** Surface distributions of salinity (a), TA (b), DIC (c), aragonite saturation state ( $\Omega_{\text{Ar}}$ ) (d), sea-ice-melt fraction ( $f_{\text{SIM}}$ ) (e), meteoric water fraction ( $f_{\text{MW}}$ ) (f), and  $\delta^{13}\text{C}_{\text{DIC}}$  (g, samples only collected during first half of the cruise). Nelson River is shown as a blue line. Note that  $\Omega_{\text{Ar}}$  (d) is above 1 at all stations.

offset correction could not be applied to either dataset prior to merging. Although this average TA difference represents significant variability between the two datasets, TA alterations of this magnitude do not alter the key results of this study and thus are not important in the context of this discussion. For example, a  $\pm 12.6 \mu\text{mol kg}^{-1}$  change in surface water TA at all stations results in an average change in surface water  $\Omega_{\text{Ar}}$  of  $\pm 0.12$ , with no visible change in spatial patterns throughout the Hudson Bay and with no stations moving from supersaturation to undersaturation, or vice versa. Also, patterns in  $\Omega_{\text{Ar}}$  along the coastal transect in Hudson Bay, including the depth of the saturation horizon, do not change significantly given a  $12.6 \mu\text{mol kg}^{-1}$  change in TA. Furthermore, it has to be noted that the sampling strategy used in this study was

not ideal for intercalibration purposes, since it took place in highly variable, relatively shallow waters as opposed to stable deep ocean waters.

Samples for  $\delta^{13}\text{C}_{\text{DIC}}$  determination were collected in 30 mL vacuum-sealed glass vials and spiked with 60  $\mu\text{L}$  of saturated  $\text{HgCl}_2$  solution to halt biological activity. Measurement of  $\delta^{13}\text{C}_{\text{DIC}}$  was conducted at Yale University using continuous-flow isotope-ratio-monitoring mass spectrometry (CF-irmMS) on Thermo Finnigan MAT 253 gas mass spectrometers coupled to a Thermo Electron GasBench II via a Thermo Electron ConFlo IV split interface. The analytical method has a reproducibility of better than  $\pm 0.1 \text{‰}$ . Samples for the oxygen isotopic composition of water ( $\delta^{18}\text{O}$ ) were collected in 20 mL borosilicate glass vials, sealed with

Parafilm to minimize evaporation, and stored at 4 °C. Measurements were conducted at the G.G. Hatch Stable Isotope Laboratory (University of Ottawa) using a Finnigan MAT Delta plus XP + GasBench. A 0.2 to 0.6 mL subsample was flushed with 2 % CO<sub>2</sub> in helium before being stored for at least 18 h to achieve equilibration. Stable carbon and oxygen isotope ratios are expressed in the usual delta ( $\delta$ ) notation as per mil (‰) deviation relative to the international VPDB (Vienna Pee Dee Belemnite) and V-SMOW (Vienna Standard Mean Ocean Water) standards, respectively. Salinity samples were analyzed on board the *Amundsen* using a Guildline 8004B Autosol Laboratory salinometer calibrated with standard seawater from the International Association for the Physical Sciences of the Oceans (IAPSO).

The fractions of sea-ice meltwater ( $f_{SIM}$ ) and meteoric water ( $f_{MW}$ ) are calculated using bottle salinities and  $\delta^{18}O$  in a three-end-member mixing model. The methods, equations, and end-member values (for seawater, sea-ice meltwater, and meteoric water) used in the model are identical to those described by Granskog et al. (2011).

## 4 Results and discussions

### 4.1 Surface distributions

Surface distributions within Hudson Bay (Fig. 2) reveal the dominant role that freshwater input plays in altering the carbonate system parameters of surface waters, particularly in the southern and eastern parts of the bay. Distributions of TA (Fig. 2b), DIC (Fig. 2c), and  $\Omega_{Ar}$  (Fig. 2d) mimic that of salinity (Fig. 2a), with maxima in the high-salinity waters of the Hudson and Foxe straits and minima along the southern coast of Hudson Bay. One notable exception, however, is near the Nelson River (Fig. 1), where stations exhibit low salinities but relatively high DIC, TA, and  $\Omega_{Ar}$ . The dilution of carbonate parameters by freshwater is more pronounced for sea-ice melt (DIC and TA 300–600  $\mu\text{mol kg}^{-1}$ ; e.g., Miller et al., 2011) compared to river outflow (river DIC and TA  $\sim$  700–1800  $\mu\text{mol kg}^{-1}$ ; Azetsu-Scott et al., 2014, and this study), and thus distributions of DIC, TA, and  $\Omega_{Ar}$  in the southern Hudson Bay likely reflect the variable impacts of river runoff and sea-ice melt on the carbonate system.

The Nelson River has the highest freshwater discharge of any single river in the Hudson Bay system, and nearly half of the river runoff into Hudson Bay enters via James Bay. These hydrographical features are well illustrated by the distribution of meteoric water fractions ( $f_{MW}$ ) throughout the region (Fig. 2f). In contrast, the fractions of sea-ice melt ( $f_{SIM}$ ) are highest along the southern coast of Hudson Bay (Fig. 2e), near the comparatively small Severn and Winisk rivers (with respective discharges one-quarter and one-sixth that of the Nelson River, Table 1). This region of high  $f_{SIM}$  corresponds well to the observed sea-ice distributions shown in Fig. 1. It is important to note that the

high positive  $f_{SIM}$  observed near the Nelson River is due to the use of a single flow-averaged  $\delta^{18}O$  end-member for meteoric water (−14 ‰, Granskog et al., 2011) near a river with a considerably higher  $\delta^{18}O$  (−10.8 ‰, Table 1). Overall, riverine  $\delta^{18}O$  signatures measured here agree well with those observed in previous studies, especially when comparing measurements made in/around the month of July (Table 1). Also note that, despite considerable freshwater input near James Bay, aragonite remains supersaturated ( $\Omega_{Ar} > 1$ ) at all stations in surface waters (Fig. 2d).

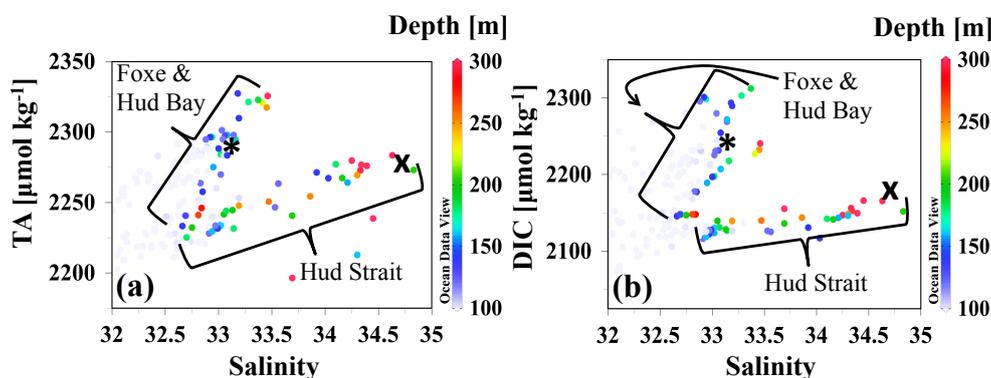

The surface distributions shown in Fig. 2 also align with the general circulation patterns of the Hudson Bay system. For example, differences can be seen between stations in the northern part of Hudson Strait, where Labrador Sea waters with characteristically high salinity, DIC, and TA flow into the Hudson Bay system, and stations at the southern side of the strait, where Hudson Bay outflow with lower salinity and TA, as well as higher  $f_{MW}$ , travels east towards the Labrador Sea. The high-salinity water in northwestern Hudson Bay represents water recently introduced from Foxe and Hudson straits, with salinities generally decreasing in a counterclockwise fashion due to freshwater inputs. At the mouth of James Bay, the salinity and carbonate parameters are higher on the western edge, where waters enter the bay, compared to the eastern edge, where waters altered by large James Bay rivers exit back into Hudson Bay. At the eastern edge of the mouth of James Bay, we recorded the minimum salinity ( $S = 21.71$ ), TA (1705  $\mu\text{mol kg}^{-1}$ ), and DIC (1624  $\mu\text{mol kg}^{-1}$ ), as well as the second lowest  $\Omega_{Ar}$  (1.04), among the “seawater” samples from our entire study.

The surface distributions of carbonate parameters throughout the Hudson Bay system are similar to those reported by Azetsu-Scott et al. (2014) for September 2005. Concentrations within Hudson Strait and Foxe Strait are comparable, and the north–south gradient within Hudson Strait is apparent in both years. Within Hudson Bay, concentrations are distinctively lower than in waters outside the bay, with values decreasing further from the northwest toward the southeast. Aragonite saturation ( $\Omega_{Ar}$ ) in surface waters does not show any significant differences between 2005 and 2010, with surface waters approaching saturation at the mouth of James Bay in both years. However, subtle differences do exist between these datasets. Stations in southern Hudson Bay have lower salinity, DIC, TA, and  $\Omega_{Ar}$  in 2010, whereas stations located further downstream, near the eastern edge of the bay, have lower values in 2005. Rather than reflecting basin-wide changes over the 5-year period, these differences can be ascribed to the seasonal timing of sample collection and general circulation patterns. That is, stations along the southern coast are impacted by substantial SIM in July as the remaining ice is melting, and the cyclonic circulation is capable of transporting such low-salinity water along the eastern edge of Hudson Bay over a 2-month period (i.e., from July to September; cf. Granskog et al., 2009).

The \* represents the end-member properties of Pacific-origin Upper Halocline Water ( $S = 33.1$ ,  $\text{TA} = 2283 \mu\text{mol kg}^{-1}$ ,  $\text{DIC} = 2236 \mu\text{mol kg}^{-1}$ ) and the black “x” represents Atlantic Water ( $S = 34.8$ ,  $\text{TA} = 2301 \mu\text{mol kg}^{-1}$ ,  $\text{DIC} = 2154 \mu\text{mol kg}^{-1}$ ), as defined by Shadwick et al. (2011). Hud Bay: Hudson Bay samples; Foxe: Foxe Strait samples; Hud Strait: Hudson Strait samples.

## 4.2 Hudson Bay source waters

The main conduits for Pacific and Atlantic waters to the Hudson Bay system (HBS) are Fury and Hecla Strait (located north of Foxe Strait) and Hudson Strait, respectively. Yet it remains unclear whether Hudson Bay is composed primarily of Pacific or Atlantic waters. Jones et al. (2003) surmised that Pacific waters were more prevalent in Hudson Bay but were

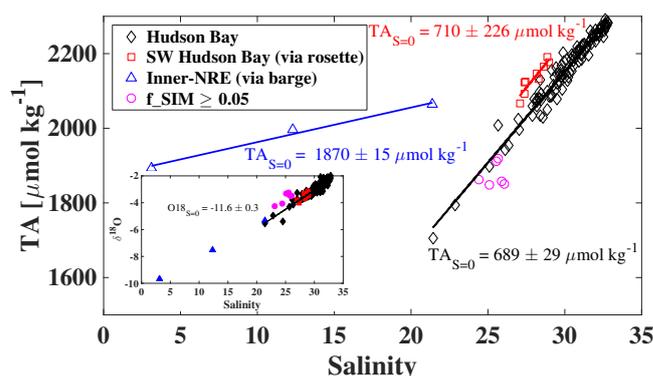

unable to provide conclusive evidence, due to limitations in the quantity and quality of their data. In regions like Hudson Bay, with multiple seawater and freshwater end-members, mass-balance calculations for unraveling freshwater components are particularly complicated, and in contrast to systems such as the coastal Beaufort Sea, where three rather distinct end-members (the Mackenzie River, sea-ice melt, and a primarily Pacific polar mixed layer) can be defined by two trac-

ers (Macdonald et al., 1995), a similarly rigorous analysis in Hudson Bay would require additional end-members and tracers.

When examining the relationship between TA and salinity throughout the HBS (Fig. 3a), waters below 100 m depth in Hudson Bay are indistinguishable from those in Foxe Strait, and both are distinctly different from deep waters in Hudson Strait. Furthermore, data from Hudson Bay and Foxe Strait are well aligned with the Pacific water end-member, while data from Hudson Strait fall along a mixing line with the Atlantic water end-member (Shadwick et al., 2011; Fig. 3a). This indicates that deep water from Hudson Strait does not enter Foxe Strait and that the vast majority of water that flows over the 185 m sill into Hudson Bay is likely of Pacific origin. In addition, some samples in the Hudson Bay/Foxe Strait dataset have higher salinity and TA than the Pacific water end-member, yet still fall along the extension of the general mixing line (Fig. 3a), suggesting an additional source of both TA and salinity. One plausible source of excess TA and salinity in deep waters is from brine rejection. It is known that deep water formation occurs in Foxe Basin polynyas, and this water can flow into Foxe Strait and potentially further into Hudson Bay (Defossez et al., 2010). However, there is evidence in Hudson Bay that deep waters can also form locally due to brine rejection (Granskog et al., 2011). The same general patterns are shown in a plot of deep water DIC against salinity (Fig. 3b), except that distinctly higher DIC is observed in Hudson Bay compared to Foxe Strait due to the build-up of respiratory DIC in Hudson Bay, which is discussed in greater detail below.

### 4.3 Freshwater inputs

Prior studies have revealed the importance of watershed geology in governing the highly variable compositions of Hudson Bay rivers (Mundy et al., 2010; Granskog et al., 2011; Azetsu-Scott et al., 2014; see also Thomas and Schneider, 1999), yet relatively little is known regarding the impact of varying river inputs on the inorganic carbon system of Hudson Bay. Variations in TA with salinity in the top 60 m of the water column of Hudson Bay (Fig. 4) reveal two distinct freshwater end-members: a lower TA end-member of  $\sim 700 \mu\text{mol kg}^{-1}$ , corresponding to the vast majority of stations in the bay, and a high-TA end-member of  $\sim 1900 \mu\text{mol kg}^{-1}$  for samples collected within the Nelson River estuary (NRE, Figs. 1 and 5). Figure 4 also highlights the various impacts of sea-ice melt, as samples with high  $f_{\text{SIM}}$  (purple circles) show distinct positive deviations from the  $\delta^{18}\text{O}$  vs. salinity mixing line (Fig. 4, inset), as well as negative deviations from the TA vs. salinity mixing line, due to the enriched  $\delta^{18}\text{O}$  signature ( $\delta^{18}\text{O}_{\text{SIM}} = 0\text{‰}$ ) and low TA concentration characteristic of sea-ice melt. The negative TA deviation in sea-ice meltwaters also indicates that there is no significant source of TA from the dissolution of ikaite

**Figure 4.** Hudson Bay TA vs. salinity ( $S$ ) in the upper 60 m of the water column (which should contain seasonal freshwater inputs; see Granskog et al., 2011). Hudson Bay stations (black diamonds, regression line  $\text{TA} = 48.8 \times S + 689.2$ ) do not include the station located northeast of the sill in the central channel (see Fig. 1). Stations in southwestern Hudson Bay (red squares, regression line  $\text{TA} = 50.9 \times S + 225.8$ ) refer to “705” stations (see Fig. 5), and station 706 slightly further north (see Fig. 1), while inner Nelson River estuary stations (“Inner-NRE”; blue triangles, regression line  $\text{TA} = 9.3 \times S + 1870.0$ ) refer to “B” stations shown in Fig. 5. Riverine end-members (TA at zero salinity, or  $\text{TA}_{S=0}$ ) and their corresponding uncertainties are calculated using linear least-squares regression and the error associated with the linear fit, respectively. Inset: Hudson Bay  $\delta^{18}\text{O}$  vs. salinity with same sample legend as the main figure (symbols are filled for clarity). The regression line ( $\delta^{18}\text{O} = 0.3 \times S - 11.6$ ) is placed through Hudson Bay samples. It is important to note that, for some surface water samples,  $\delta^{18}\text{O}$  and its corresponding salinity were collected independently of TA and its corresponding salinity; therefore, high  $f_{\text{SIM}}$  (calculated using  $\delta^{18}\text{O}$ ) may not be present in TA samples. This may explain why some samples with high  $f_{\text{SIM}}$  show little to no negative deviation in TA (purple circles).

( $\text{CaCO}_3$ ) during sea-ice melt (see Rysgaard et al., 2011) in this area.

Considering that samples with potential inputs of brine (i.e., deeper waters) and discernable sea-ice melt input (i.e., stations with  $f_{\text{SIM}} \geq 0.05$ ) are not included in the best-fit regressions, the lower alkalinity end-member (that is,  $\text{TA} = 689 \mu\text{mol kg}^{-1}$ ) likely represents the average riverine TA for the entire Hudson Bay. This end-member aligns with the prior estimate for “rivers” of  $754 \mu\text{mol kg}^{-1}$ , also derived from regression lines of samples collected within the bay and not from the rivers, themselves, along the eastern shore of Hudson Bay (Azetsu-Scott et al., 2014). Stations in southwestern Hudson Bay, nearest to the Churchill, Nelson, and Hayes rivers (Fig. 4, red squares, “705” stations and station 706; see Figs. 1 and 5), have a similar salinity–TA relationship to that observed throughout Hudson Bay but are vertically offset to a slightly elevated TA. This TA offset is not related to the merging of the two TA datasets, as the stations labeled as “SW Hudson Bay” (see Fig. 4) comprise a small subset of the TA data measured at IOS. Also, the magnitude

of this vertical TA offset ( $\sim 80 \mu\text{mol kg}^{-1}$ ) is much larger than the average deviation observed between the datasets. Instead, this offset likely indicates input of carbonate ion from the dissolution of carbonate minerals. For salinity vs. DIC, the same offset is visible but is less pronounced, which also points towards benthic carbonate ion addition. Azetsu-Scott et al. (2014) attributed their observations of high TA in the deep waters of southwestern Hudson Bay to dissolution of the carbonate-rich bedrock (defined as the Hudson Bay Lowland) that underlies this area of the bay, as well as much of the Nelson River drainage basin.

We attribute the high-TA end-member ( $1870 \mu\text{mol kg}^{-1}$ ) to the Nelson River. A similarly high TA end-member has been reported for the Mackenzie River ( $1540 \mu\text{mol kg}^{-1}$ ; Cooper et al., 2008) and time-series measurements collected from the Churchill River (Fig. 1) during the summer of 2007 reveal an average TA of  $1394 \pm 80 \mu\text{mol kg}^{-1}$  (Stainton, 2009). According to Mundy et al. (2010), the Churchill, Nelson, and Hayes rivers (Fig. 1) have dissolved organic carbon (DOC) concentrations that are 2–6 times greater than other Hudson Bay rivers (Table 1), and these authors attributed variability in riverine DOC to the vastly differing watershed geologies throughout the Hudson Bay region. The weathering of organic-rich soils throughout the extensive Nelson River drainage basin would contribute to higher riverine DIC and TA compared to rivers further north with drainage basins in the relatively organic-poor Arctic tundra. Furthermore, weathering processes become more active in subarctic, or even temperate, regions of the Hudson Bay drainage area, yielding higher TA inputs from those regions than from polar regions. This regional dependence on riverine composition is also observed in the  $\delta^{18}\text{O}$  signatures, both across the basin and within a single river catchment, with the southwestern rivers having distinctly less depleted  $\delta^{18}\text{O}$  signatures than the rivers further north (Table 1; see also Granskog et al., 2011, and Smith et al., 2015). Nevertheless, the TA end-member calculated here is substantially higher than the prior estimate for the Nelson River ( $1022 \mu\text{mol kg}^{-1}$ ; Azetsu-Scott et al., 2014), and we think this discrepancy is due to sampling depth within this highly stratified system, as well as to the fact that our samples extended further up the estuary, into fresher waters.

Data obtained via rosette sampling in southwestern Hudson Bay (Fig. 4, red squares) yield a riverine TA end-member of  $710 \mu\text{mol kg}^{-1}$ , and the uncertainty on this value places it in the same range as the end-member calculated for the rest of Hudson Bay. According to the CTD data, samples from southwestern Hudson Bay were collected between 1.4 and 10.3 m depth, with the former being considered “surface” samples. In contrast, samples collected from the surface in the inner NRE using the small barge yield an end-member of  $1870 \mu\text{mol kg}^{-1}$ . Given the close proximity of these inner NRE stations to others in southwestern Hudson Bay, the discrepancy in end-members indicates that surface samples collected via the rosette captured a different water mass than

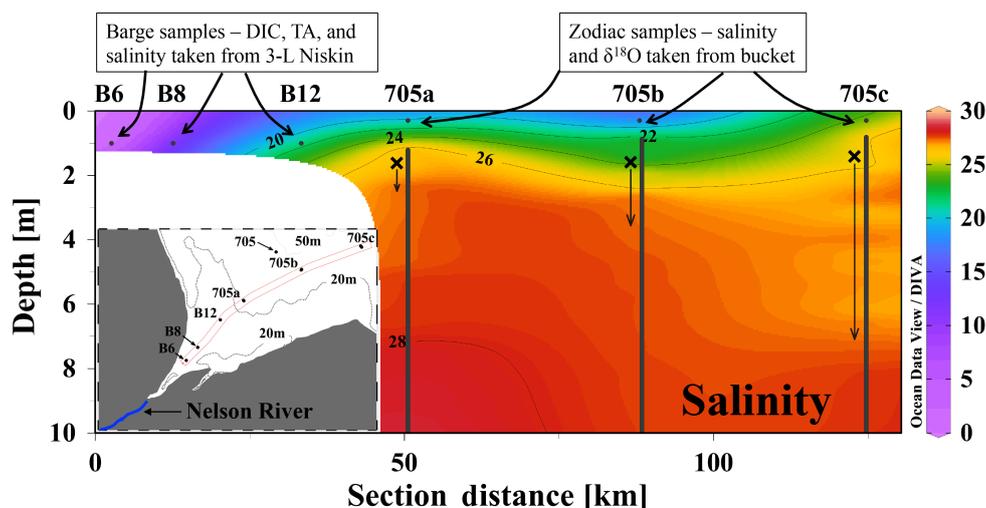

those collected via the small barge. This is illustrated further using a cross section of salinity in the NRE (Fig. 5).

Salinity across the NRE, as measured in situ by the CTD attached to the rosette system, and as measured from discrete surface bottle samples collected either from the barge or using a bucket dropped from the bow, is shown in Fig. 5. At stations 705a, b, and c, salinity samples collected from surface waters via bucket have considerably lower salinities than any waters measured by the CTD. Furthermore, according to the CTD pressure data, surface Niskin bottles from stations 705a, b, and c were closed at 1.6, 1.6 and 1.4 m respectively (Fig. 5, black X's), but the salinities measured in these Niskin bottles correspond to the CTD salinities observed at depths of 2.5, 3.6, and 7.1 m, respectively (Fig. 5, vertical black arrows), indicating that the Niskin bottles contained some deeper waters entrained into the surface by the upward-moving rosette. This highlights the importance of taking bottle salinity samples from Niskins in parallel with parameters such as DIC and TA, particularly in highly stratified waters. Here, all DIC and TA samples collected in southwestern Hudson Bay are accompanied by a high-precision salinity sample taken from the same Niskin bottle.

At stations B6, B8, and B12 (Fig. 5), salinities measured using the 3 L Niskin bottles (deployed to 1 m depth from the small barge) are very low and show an increasing salinity with distance away from the Nelson River mouth that is consistent with the bucket samples collected at stations 705a, b, and c. Clearly, the samples collected from the small boats (barge and Zodiac) captured low-salinity waters very near the surface, while the “surface” rosette bottles captured water from a deeper layer with considerably higher salinities. Assuming the low-salinity layer represents the Nelson River plume, this water is only accurately captured using the samples taken via small boats, which explains why samples taken via barge in the inner NRE have a markedly different TA vs. salinity relationship from samples taken via rosette throughout the remainder of Hudson Bay (Fig. 4). Additionally, at station 705c (Fig. 5), the bucket sample near the surface does not appear to have captured the low-salinity river plume, demonstrating the extent to which river inputs are constrained to the coastline during cyclonic transport around the bay (Fig. 1). Large CTD salinity gradients in the upper 2 m were observed at other stations along the southern coast, suggesting that data from the surface Niskin bottle at these stations may also not fully reflect the true “surface water” properties.

#### 4.4 Coastal transect

Hudson Bay waters undergo significant compositional changes during their cyclonic transit around the basin (Granskog et al., 2009; Mundy et al., 2010). Here, we focus specifically on changes in the carbonate system along a coastal transect that follows the general counterclockwise circulation pattern from northwestern Hudson Bay to the

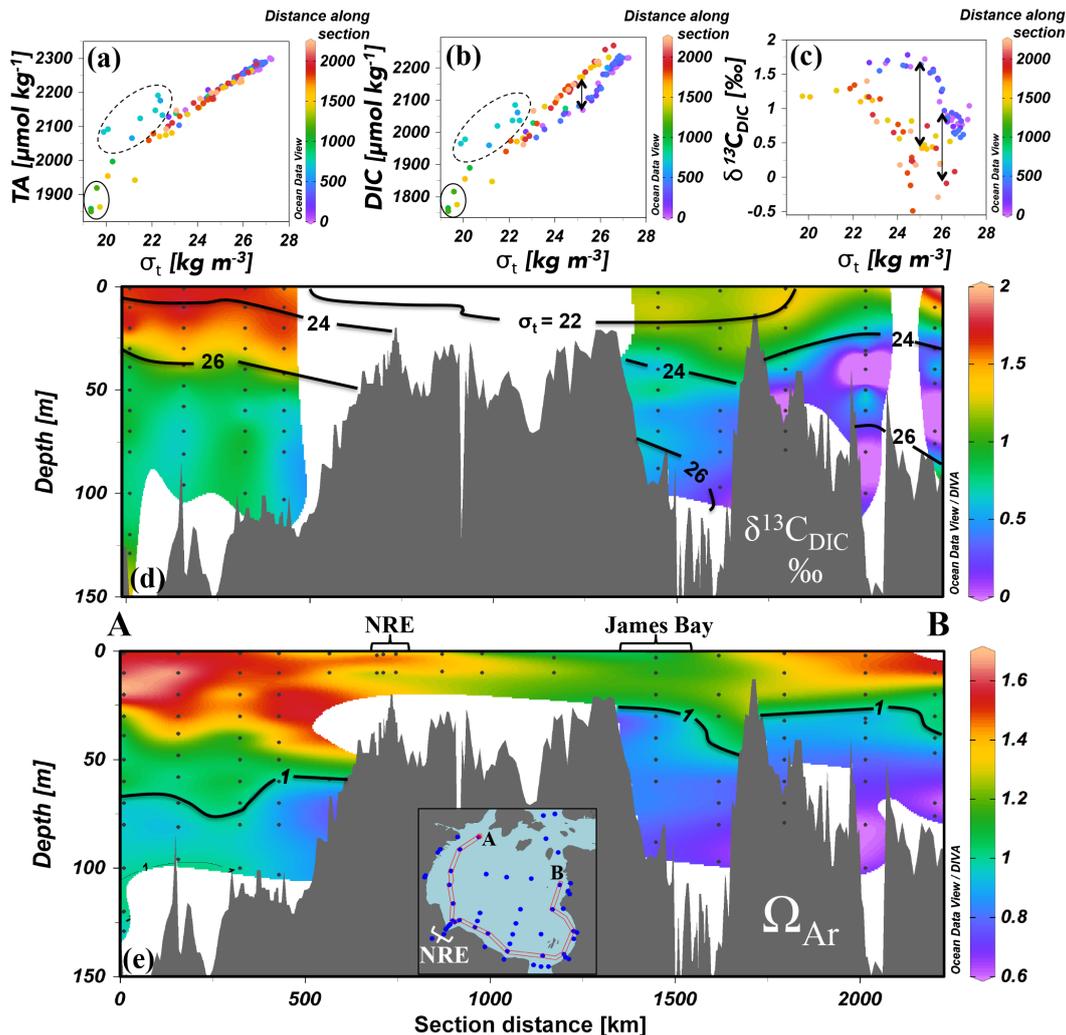

**Figure 5.** Salinity cross section (top 10 m) in the Nelson River estuary (NRE). Location of transect is shown by the inset map in the lower right (see Fig. 1 for location of the NRE within Hudson Bay). Vertical black lines represent CTD profiles, while black dots (depths  $\leq 1$  m) represent samples taken independently using the single 3 L Niskin ( $\sim 1$  m depth, stations B6, B8, B12) and samples taken using the bucket ( $\sim 0.3$  m depth at stations 705 a, b, c). Black X's show the depth where surface Niskin bottles were closed, as recorded by the CTD's pressure sensor, while the black vertical arrows extend to the depth where salinities in the Niskin bottles match the salinity recorded by the CTD. Prior to closing each Niskin bottle, the rosette was held at the target depth for 1 min to allow for adequate flushing and stabilization (Y. Gratton, personal communication, 2016). At all three rosette stations (705 a, b, c), Niskin bottle salinities are markedly higher than the CTD salinities at the closure depth, suggesting that higher-salinity waters were entrained into surface waters by the rosette system.

northeast (Fig. 6, transect A–B). For stations within this transect, TA, DIC, and  $\delta^{13}\text{C}_{\text{DIC}}$  are plotted against in situ density anomaly ( $\sigma_t$ , observed density  $-1000 \text{ kg m}^{-3}$ ) to illustrate deviations at constant density levels (Fig. 6a–c). For TA (Fig. 6a), there is little variability between stations along the transect and the vast majority of the data fall along the river mixing line. There are, however, two notable exceptions: the first being high-TA deviations at stations within the NRE that we attribute to dissolution of carbonate minerals, and the second being low-TA deviations in samples with high sea-ice melt fractions ( $f_{\text{SIM}} \geq 0.05$ ), all of which are measured at or near the surface along the southern coast.

For along-transect DIC (Fig. 6b), the impacts of both freshwater input and biological activity are apparent. Similar to TA, positive deviations from a general river mixing line are observed in the NRE, as are negative deviations along the southern coast, but a distinct increase in DIC is also visible along the transect due to a build-up of respiratory DIC in sub-surface waters. The maximum offset between waters along the west coast (blue–purple points) and the east coast (red–yellow points) is between the 24 and 26  $\text{kg m}^{-3} \sigma_t$  horizons, indicating that organic matter respiration rates are highest at these density levels. The structures of these density horizons along the coastal transect are shown in Fig. 6d. The lack of any visible offset in bottom water TA suggests that any products of anaerobic respiration that may be produced in sediments are not transported into the water column.

Unlike TA and DIC, freshwater input appears to play a relatively minor role in governing variability in the stable carbon isotope signature of DIC ( $\delta^{13}\text{C}_{\text{DIC}}$ ) of Hudson Bay waters (Fig. 6c). This may be due to the fact that Hudson Bay rivers are very isotopically enriched (average  $\delta^{13}\text{C}_{\text{DIC}} = -3.2\text{‰}$ , Table 1) compared to other coastal regions (North Sea  $\delta^{13}\text{C}_{\text{DIC}} = -12$  to  $-16\text{‰}$ ; Burt et al., 2016) and thus are much closer to typical seawater values ( $\sim 0$ – $2\text{‰}$ ). Biogenic soils are highly depleted in  $\delta^{13}\text{C}_{\text{DIC}}$  ( $\sim -25\text{‰}$ ), while carbonate bedrock has a  $\delta^{13}\text{C}_{\text{DIC}}$  near  $0\text{‰}$  (Spiker, 1980). Given that the majority of Hudson Bay rivers have rather low DOC (Mundy et al., 2010) and that much of the bedrock surrounding the bay is carbonate-rich (Ross et al., 2011), it is unsurprising that Hudson Bay rivers are isotopically enriched compared to other regions. However,  $\delta^{13}\text{C}_{\text{DIC}}$  was not sampled along the southern coast; thus, the Churchill, Nelson, and Hayes rivers, which are likely more depleted in  $\delta^{13}\text{C}_{\text{DIC}}$ , are not included in Table 1 and are not well represented in Fig. 6c and d.

Conversely, the  $\delta^{13}\text{C}_{\text{DIC}}$  distributions in Fig. 6c do highlight the impact of biological activity along the coastal transect. Waters become isotopically lighter during their transit around the basin, because respiration of organic matter releases isotopically light DIC into the water column. In accordance with Fig. 6b, relative changes between waters along the western shore (blue–purple points) and eastern shore (red–yellow points) are greatest in intermediate waters. In the North Sea, Burt et al. (2016) showed that a respiratory

**Figure 6.** Variations in TA (a), DIC (b), and  $\delta^{13}\text{C}_{\text{DIC}}$  (c) with in situ density anomaly ( $\sigma_t$ , observed density –  $1000 \text{ kg m}^{-3}$ ) along the northwest–northeast (A–B) coastal transect (inset map of transect is shown in lower panel). Dashed ellipses surround data within the NRE, while solid ellipses surround data with  $f_{\text{SIM}} \geq 0.05$  (located along southern coastline). Vertical arrows illustrate differences in DIC and  $\delta^{13}\text{C}_{\text{DIC}}$  between waters in western Hudson Bay (blue–purple points) and eastern Hudson Bay (red–yellow points). Note that  $\delta^{13}\text{C}_{\text{DIC}}$  was not sampled during the latter part of the cruise (i.e., along the southern coast). (d) Cross section of  $\delta^{13}\text{C}_{\text{DIC}}$  along the coastal transect with isopycnals of in situ density anomaly ( $\sigma_t$ ,  $\text{kg m}^{-3}$ ). (e) Cross section of  $\Omega_{\text{Ar}}$  with solid line representing the aragonite saturation horizon ( $\Omega_{\text{Ar}} = 1$ ).

DIC increase of  $1 \mu\text{mol kg}^{-1}$  could be roughly equated to a  $0.012 \text{ ‰}$  decrease in  $\delta^{13}\text{C}_{\text{DIC}}$ . Taking this ratio, and assuming that waters are transported along lines of constant density, changes in  $\delta^{13}\text{C}_{\text{DIC}}$  at intermediate depths (between  $\sim 25$  and  $50$  m, at  $\sigma_t = 25 \text{ kg m}^{-3}$ ; see Fig. 6c and d) between western and eastern waters equate to an addition of approximately  $110 \mu\text{mol kg}^{-1}$  DIC. Observed increases in DIC at the same density level (Fig. 6b) are approximately  $90 \mu\text{mol kg}^{-1}$ , which is comparable given the rough nature of this calculation. In deeper waters (between  $\sim 40$  and  $100$  m, at  $\sigma_t = 26 \text{ kg m}^{-3}$ ; see Fig. 6d), both observed DIC increases (shown in Fig. 6b) and increases based on differences in  $\delta^{13}\text{C}_{\text{DIC}}$  (shown in Fig. 6c) equate to  $\sim 70 \mu\text{mol kg}^{-1}$ . It is

important to note that the ratio taken from Burt et al. (2016) assumes that all respired organic matter is of marine origin, and although the  $\delta^{13}\text{C}_{\text{DIC}}$  derived from respired terrestrial organic matter may have a similar isotopic signature to that of marine-derived material, it is not clear how a significant fraction of terrestrial material in the organic matter pool would affect this first-order calculation. However, in the coastal marine system, the organic matter turnover (i.e., cycles of production and respiration) is generally rapid, and thus any terrestrial signature within the organic matter pool will quickly become difficult to detect.

The effects of biological activity, sea-ice melt, and variable riverine input on the carbonate system of Hudson Bay

are well summarized in the coastal transect of aragonite saturation state ( $\Omega_{Ar}$ ) shown in Fig. 6e. In surface waters,  $\Omega_{Ar}$  is high in the northwest but decreases along the southern coast due to the dilution of both TA and DIC by freshwater input. In the NRE,  $\Omega_{Ar}$  remains high despite low salinities (see Fig. 2a, d) because of carbonate dissolution either in the drainage basin (as visible in the high alkalinity of the Nelson River) or in the sediments in the estuary (Fig. 4). Surface waters near James Bay show minima in  $\Omega_{Ar}$ , likely due to the strong sea-ice melt signal in these waters, as well as large inflows of low-alkalinity river waters (see Fig. 2). Along the eastern shore, surface water  $\Omega_{Ar}$  is comparable to (i.e., only slightly lower than) values along the west coast. This is likely due to the fact that the sea-ice meltwaters, which dilute TA and DIC to a much greater degree than river input, have yet to be transported to these stations. In September 2005, surface water  $\Omega_{Ar}$  along the southern coast was higher than observed here, while further downstream along the eastern coast,  $\Omega_{Ar}$  was lower than observed here (Azetsu-Scott et al., 2014). This may simply reflect the transport of low- $\Omega_{Ar}$  sea-ice meltwaters from the southern coast in July to the eastern shore by September. In accordance with this, Granskog et al. (2009) noted that in October 2005, virtually no sea-ice melt was observed along the southern shore, further suggesting that these waters had been transported northeast by the coastal current.

Focusing on subsurface waters along the transect, the saturation horizon shoals significantly from 60–70 m along the west coast to 30–40 m along the east coast. Furthermore, deep waters along the west coast are only slightly undersaturated, while deep waters along the east coast are heavily undersaturated. These patterns likely reflect the build-up of respiratory DIC in deep waters during transit around Hudson Bay, as aerobic respiration releases DIC while consuming TA, thus causing a relatively strong decrease in  $\Omega_{Ar}$ . Deep waters along the eastern shore are likely older than waters along the western shore, allowing the products of aerobic respiration to build up over time. Exchange with open ocean waters is limited by the shallow sills at the mouth of Hudson Bay, and very low saturation states are observed at deeper stations in the central Bay, as well as in the coastal transect (Fig. 6e).

Subsurface  $\Omega_{Ar}$ , both along the coastal transect (Fig. 6e) and in a cross-basin section (not shown), is very similar to the 2005 distributions shown by Azetsu-Scott et al. (2014), suggesting that the acidification state of Hudson Bay had not changed discernibly between 2005 and 2010. However, with only two such datasets taken at slightly different times of the year, more information is required to make conclusive statements regarding acidification rates in this region.

## 5 Conclusions

This work contributes insight into important carbon cycling processes in a region of the Arctic where biogeochemical data are sparse. The Hudson Bay is home to a vast number of ecologically important species; thus, an improved understanding of the key processes affecting the carbonate system, and thereby the ecosystem, in the bay is crucial. Surface distributions reveal the importance of variable freshwater inputs from runoff and sea-ice melt in altering the carbonate system, especially in the southern part of Hudson Bay. Rivers draining into Hudson Bay have highly variable DIC and TA, a highly enriched  $\delta^{13}C_{DIC}$  signature compared to other regions, and  $\delta^{18}O$  signatures that show a strong regional dependence. Given these results, we suggest that future studies in Hudson Bay undergo extensive sampling that is dedicated to making robust estimates of multiple, regionally defined riverine  $\delta^{18}O$  end-members. This study also shows that the deep Hudson Bay (a) is primarily filled with waters of Pacific origin from the Canadian Arctic Archipelago and (b) thus has limited interaction with Atlantic waters in the deep Hudson Strait, which supports the preliminary findings of Jones et al. (2003). Within Hudson Bay, the salinity vs. TA relationship indicates mixing between the Pacific waters and river waters with relatively low TA, compared to rivers at lower latitudes. Negative deviations from the mixing line are due to dilution from sea-ice melt, whereas positive deviations in the Nelson River estuary point to carbonate mineral dissolution. Direct sampling of river DIC and TA throughout the bay, as well as detailed surface water sampling (i.e., from multiple platforms) in highly stratified estuarine waters, is needed to better understand exactly how river inputs alter the carbonate system parameters of Hudson Bay. This is especially important given that river input into Hudson Bay is likely changing significantly due to climate change and, perhaps more importantly, continued hydroelectric development in the region. Finally,  $\Omega_{Ar}$  in deep waters show no discernable change from 2005 levels, and slight changes in surface water  $\Omega_{Ar}$  can be attributed to seasonal variability.

## 6 Data availability

The dataset is currently being prepared for submission to the Carbon Dioxide Information Analysis Center (CDIAC). The full dataset is also available via email to the corresponding author (William J. Burt). Furthermore, the data has been made available to the ArcticNet community, as is required by the funding agency.

*Author contributions.* William J. Burt – primary data analysis, primary writer of manuscript. Helmuth Thomas – assistance in data analysis, writing, and editing. Lisa A. Miller – collection and quality control of IOS data, assistance in data analysis, writing, and edit-

ing. Mats A. Granskog, Tim N. Papakyriakou, and Leah Pengelly – manuscript preparation, writing, and editorial assistance.

**Acknowledgements.** Thank you to the ArcticNet community for support and helpful feedback. Also, thanks to Conrad Koziol for collecting DIC and TA samples and to Marty Davelaar for sample analyses, as well as the captain, crew, and ArcticNet scientists aboard the CCGS *Amundsen*. Finally, thank you to L. W. Cooper and the second anonymous reviewer for thoughtful suggestions, which led to significant improvements in the revised manuscript. Mats A. Granskog was supported by the Centre for Ice, Climate and Ecosystems at the Norwegian Polar Institute and the Fram Centre Ocean Acidification Flagship research program funded by the Ministry of Climate and Environment of Norway. This research was supported by grants from NSERC and ArcticNet, as well as by Fisheries and Oceans Canada. The majority of figures were produced using Ocean Data View.
